Most of the rest of this article is devoted to a consideration of the consequences of competition in some simple situations. The bearing of these results on more complicated and realistic situations is discussed shortly at the end. The following assumptions are made: (1) Individuals are all alike: no sex, age or genetic distinctions are recognized. (2) The environment is uniform in time and space. (3) The system is closed ecologically, that is, there is no immigration or emigration. (4) The numbers are large enough for deterministic rather than stochastic equations to be used, and for the numbers to be treated as continuous variables. (5) There is no time lag in any effect.

For each species a differential equation will be written in which the left-hand term, dn/dt, represents the rate of change of the population size n in time, while the right-hand side will have one term to represent births and others to represent deaths. It is convenient at first to ignore density effects on the birth-rate and write

$$dn/dt = an \tag{1}$$

where a is a positive constant, for the birth-rate. For the death-rate from a single controlling factor for a single species write

$$-bnf(n) \tag{2}$$

where b is another positive constant and $f(n)$ is a monotonic increasing function of n such that, when n is small, $bf(n) < a$, and when n is large, $bf(n) > a$, large and small referring here to values n might conceivably have in a real population. The inclusion of the term n in the expression for a controlling factor ensures, in a system in which more than one species are being considered, that the losses of the population shall be small when the population is small, irrespective of the size of the other populations. This term is arbitrary, and the effect of using other possible terms in its place is considered later.

The equations for two species the whole mortality of which is caused by one controlling factor acting on both of them can be written as

$$\begin{aligned} dn_1/dt &= a_1n_1 - b_1n_1f(n_1,n_2) \\ dn_2/dt &= a_2n_2 - b_2n_2f(n_1,n_2) \end{aligned} \tag{3}$$

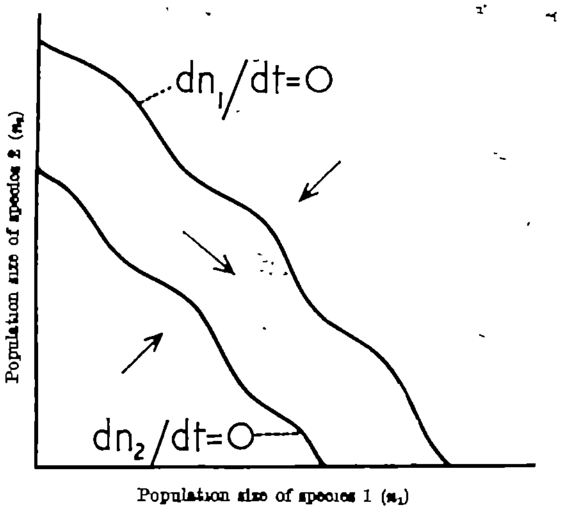
where n_1,n_2 are the population sizes of the two species, a_1,a_2,b_1,b_2 are positive constants and $f(n_1,n_2)$ is a monotonic increasing function, symmetrical in n_1 and n_2, and with $f(n,0) = f(n)$. Because of assumption 1 above, that all the individuals are the same, n_1 and n_2 can be any suitable measures which make $f(n_1,n_2)$ symmetrical. Equations (3) are the same as equations (2) of Chin[10] and can be contrasted with the equations of competition given by Philip[11] and the authors he quotes. These can be written

$$\begin{aligned} dn_1/dt &= a_1n_1 - b_1n_1(n_1 + c_1n_2) \\ dn_2/dt &= a_2n_2 - b_2n_2(n_2 + c_2n_1) \end{aligned} \tag{4}$$

where c_1 and c_2 are positive constants. It will be noted that these differ from (3) in that the monotonic function in parenthesis is assumed to be linear and that it it is not symmetrical. Consequently the solution of (4), which allows both species to survive, does not exist for (3). Ecologically, (4) does not necessarily represent two species with but one controlling factor, and the use of a linear function has no biological justification.

The solution of equations (3) has been given by Chin and others, and is that if $a_1/b_1 > a_2/b_2$ species 1 will survive and species 2 die out and conversely. For the rest of this paper species 1 will be assumed to survive. The situation is shown in Fig. 1. The axes represent the numbers n_1,n_2. The lines across the figure are the loci of $dn_1/dt = 0$ and $dn_2/dt = 0$, and are drawn as undulating lines as $f(n_1,n_2)$ is only loosely defined. The arrows show the direction of movement of a point representing the joint population in each of the three zones defined by the two curves. When $a_1/b_1 = a_2/b_2$ the curves coincide, and a line of neutral equilibria, analogous to the $p^2 : 2pq : q^2$ equilibrium in genetics, exists. In practice, a_1/b_1 never will be exactly equal to a_2/b_2, but note that the rate of elimination of one species by the other is a function of the difference of these two ratios, and in a stochastic model the species with the smaller ratio would sometimes be the survivor.

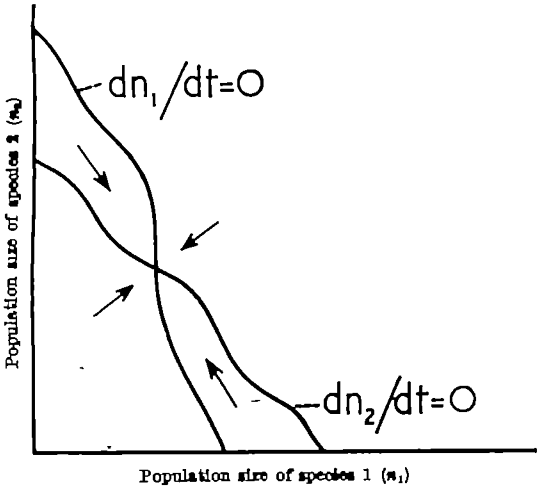
Two species, then, each with a constant birth-rate and death caused only by a single controlling factor acting simply on both of them, cannot coexist. Consider next the addition of a second controlling factor acting on both species or just on species 1. This means the addition of another term like (2) to



dn₁/dt=0
dn₂/dt=0
Population size of species 2 (n₂)
Population size of species 1 (n₁)

Fig. 1. A diagram to show the course of competition when one species eliminates the other

both or one of the equations (3), or, if the controlling factor acts through the birth-rate, the replacement of a in (1) by a monotonic decreasing function of n, which can be taken as equal to a for small n. In either case the locus of $dn_1/dt = 0$ in Fig. 1 will be moved towards the origin, but the movement will be greatest along the n_1 axis. It is possible that this will make the two curves intersect, giving Fig. 2. Here there is a point of stable equilibrium. This means that if two species are in competition from having a controlling factor in common, it is possible for them to reach a stable equilibrium with both species surviving, provided that at least one other controlling factor is acting. No question of different niches arises. This conclusion can be generalized to a proposition that it is possible to have as many species as controlling factors. If there are more species than controlling factors some must die out, and in many cases fewer species than there are controlling factors will be able to survive. There is no point in proving this general proposition in view of the consequences of complicating the system in other ways which are considered below.



dn₁/dt=0
dn₂/dt=0
Population size of species 2 (n₂)
Population size of species 1 (n₁)

Fig. 2. A diagram to show the course of competition leading to a balance between the two species

As has been mentioned, the term n in (2) is arbitrary; other monotonic increasing functions in n could be used instead. Those that increase faster than n can represent increased preference or habituation by the controlling factor. Rewrite the first equation of (3) as

$$d \ln n_1/dt = a_1 - b_1 f(n_1,n_2) \tag{5}$$

then the locus of $dn_1/dt = 0$, which is the same as the locus of $d \ln n_1/dt = 0$, cuts the n_1 axis at the value of n_1, which is the solution of

$$a_1/b_1 = f(n_1) \tag{6}$$

and the n_2 axis at the value of n_2 which is the solution of

$$a_1/b_1 = f(n_2) \tag{7}$$

A 'preference factor' can be included in (5) by putting another monotonic increasing function of n_1, say, $g(n_1)$, in the last term. If $g(0)$ is taken as 1, then the intersections of $dn_1/dt = 0$ with the axes become the solutions of

$$a_1/b_1 = f(n_1)g(n_1) \tag{8}$$

for the n_1 axis, and

$$a_1/b_1 = f(n_2)g(0) = f(n_2) \tag{9}$$

for the n_2 axis. $g(n_1)$ must be greater than one, so the solution of (8) is less than the solution of (6). The situation in Fig. 2 is again possible, and would of course still be possible if $g(0) \neq 1$. This time two species are in stable equilibrium although there is but a single controlling factor which acts on both. An example of this would occur if two species of snail were controlled by a single species of bird, and if the bird tended to prefer whichever snail was the commoner. Both species of snail could persist.

Terms can be added to equations (3) to represent deaths not caused by controlling factors. If an inverse density-dependent factor, a factor which causes more deaths at low densities, is included the curves of Fig. 1 can be moved so as to intersect and give a point of unstable equilibrium. Indeed, functions representing the controlling and inverse density-dependent factors could be found so that the loci of $dn_i/dt = 0$ intersected more than once, giving a series of stable and unstable equilibria, so producing another case in which two species with but one controlling factor could coexist. Such a case would not occur with functions which are likely to be found in real communities.

What would be the consequences of competition if the five assumptions listed above were abandoned? In the simple cases considered here, survival of both competitors becomes easier and more likely as more variables are considered. Further complications are likely to have the same effect, except that stochastic systems may well have fewer effective equilibria. For example, Nicholson[12] in his proposition C 12 says, "if several species of specific parasites attack a common host species in succession, the steady state may exist", or in the terminology of this paper, several species can coexist when they all have the same controlling factor and no other controlling factors if the factor acts on each at a different time. Again, Oldham[13] found that only one of the two species of snail *Cepaea nemoralis* and *C. hortensis* occurred on any particular area of sand dunes, although overlapping colonies of these two species can be found inland[14]. This suggests that the ecological situation on the sand dunes is not complicated enough to allow both species to occur together.

Finally, all systems developed here which lead to a stable equilibrium with both competing species surviving can be adapted to refer to alleles of a single species persisting in stable polymorphism.

EVIDENCE FROM MOIRÉ PATTERNS OF PACKING FAULTS IN BORON NITRIDE CRYSTALS

By DR. J. F. GOODMAN

Research Laboratory for the Physics and Chemistry of Solids, Department of Physics, Cambridge

DURING an experimental investigation on the friction properties of lamellar solids, a specimen of crystalline boron nitride was examined in the electron microscope, a Siemens Elmiskop 1. Fringes of widely varying spacing were frequently observed. These were moiré patterns of the type observed by other workers with overlapping crystals (see Pashley, Menter and Bassett[1]). However, the patterns were seen more frequently than would be expected from fortuitously overlapping crystals so the investigation was extended.

The boron nitride containing less than 0·6 per cent impurities was given by Mr. R. S. Pease[2], who prepared it in a white crystalline form. A drop of a suspension of boron nitride in alcohol was dried on a grid covered with a thin carbon film which had been stripped from a cleavage face of mica at a water surface. The plate-like crystallites tended to lie flat on the film, so that the incident electron beam was approximately perpendicular to the basal plane. The planes involved in the production of the moiré pattern are of the type (*hki*0) which are perpendicular to the basal plane. Any slight tilt of the crystals could frequently be corrected by using the stereo-holder to bring the planes into the required diffraction position.

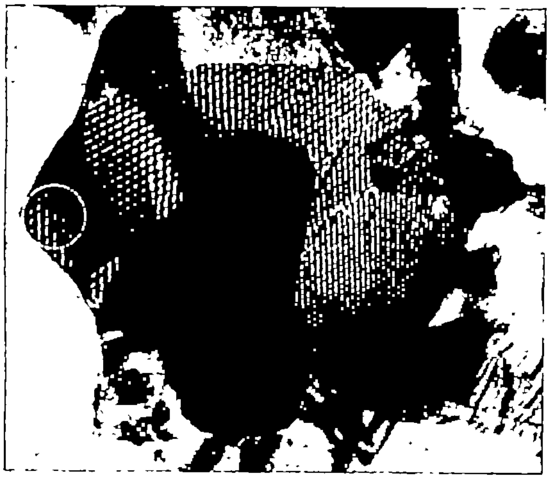

Fig. 1. Moiré pattern from boron nitride in bright field showing several sets of fringes. (× 34,000)

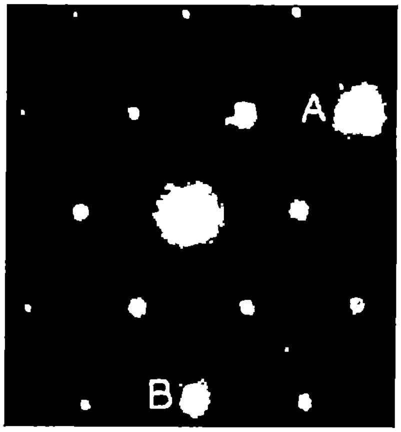

Fig. 2. Diffraction pattern from the area indicated by the circle in Fig. 1

Formation of Fringes with Boron Nitride

The crystal structure of boron nitride was completed by Pease[2]. It has a hexagonal layer lattice ($a = 2\cdot504$ A., $c = 6\cdot661$ A. at 35° C.). The layers consist of a network of hexagons of composition B_3N_3 and they are repeated along the c-axis every 3·33 A. In contrast to graphite, where alternate layers are displaced laterally, the layers in boron nitride are packed directly above one another, so that a perfect crystal may be considered to have a hexagonal array of holes extending through it parallel to the c-axis.

Fig. 1 is a moiré pattern from boron nitride showing several sets of fringes. It was obtained using bright-field illumination with a 50-μ objective aperture. The diffraction pattern obtained from the area indicated by the circle, using the technique of selected area diffraction, is shown in Fig. 2. The pattern is printed so that its orientation is the same as the micrograph. Fringes were also obtained in the dark-field image by using the objective aperture to select the diffraction spots *A* and *B*, and are shown in Figs. 3*a* and 3*b*, respectively. The fringes obtained in dark field are almost perpendicular to the planes

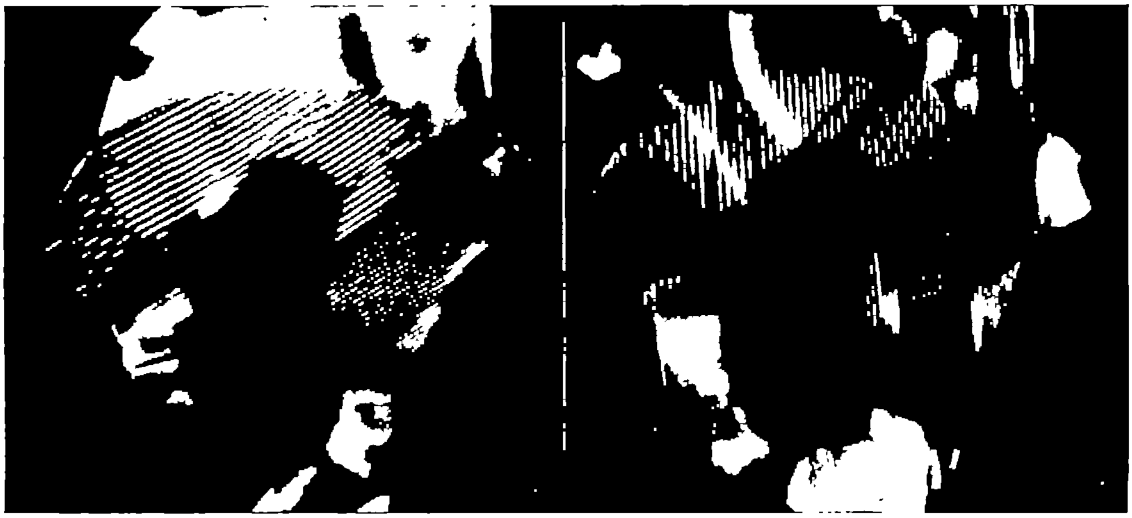

Fig. 3. (*a*) Moiré pattern in the dark field from spot *A* in Fig. 2. (*b*) Moiré pattern in the dark field from spot *B* in Fig. 2. (× 34,000)

of the type (11$\bar{2}$0) producing them, suggesting that they are formed by two crystals, one of which is twisted about the *c*-axis relative to the other. The dark-field technique has two advantages. The planes producing the fringes can be identified unambiguously, and the contrast is improved considerably since only the beams producing the fringes are allowed through the objective aperture. The planes producing the fringes of spacing about 140 A. shown in the bright-field micrograph, Fig. 4*a*, were identified by the dark-field micrograph, Fig. 4*b*, to be of the type (10$\bar{1}$0). The increased contrast in dark field clearly reveals a set of fringes of spacing approximately 60 A. on another crystallite which are almost invisible in the bright-field micrograph.

Fig. 5*a* represents two crystals, C_1 and C_2, one of which is rotated through a small angle α about an axis parallel to the incident beam relative to the other. The image observed in bright field is caused by interference of the undeviated beam L with the doubly diffracted beam M. Fringes are formed perpendicular to the planes producing them and the fringe spacing S is given by $S = d/\alpha$, where d is the spacing of the planes involved in the double diffraction (Dowell, Farrant and Rees[3]). The image obtained in dark field is considered to arise from interference of the two primary diffracted beams P and Q. Fig. 5*b* shows a section through the reciprocal lattice of boron nitride perpendicular to the basal plane, and Fig. 5*c* a section through the reciprocal lattice

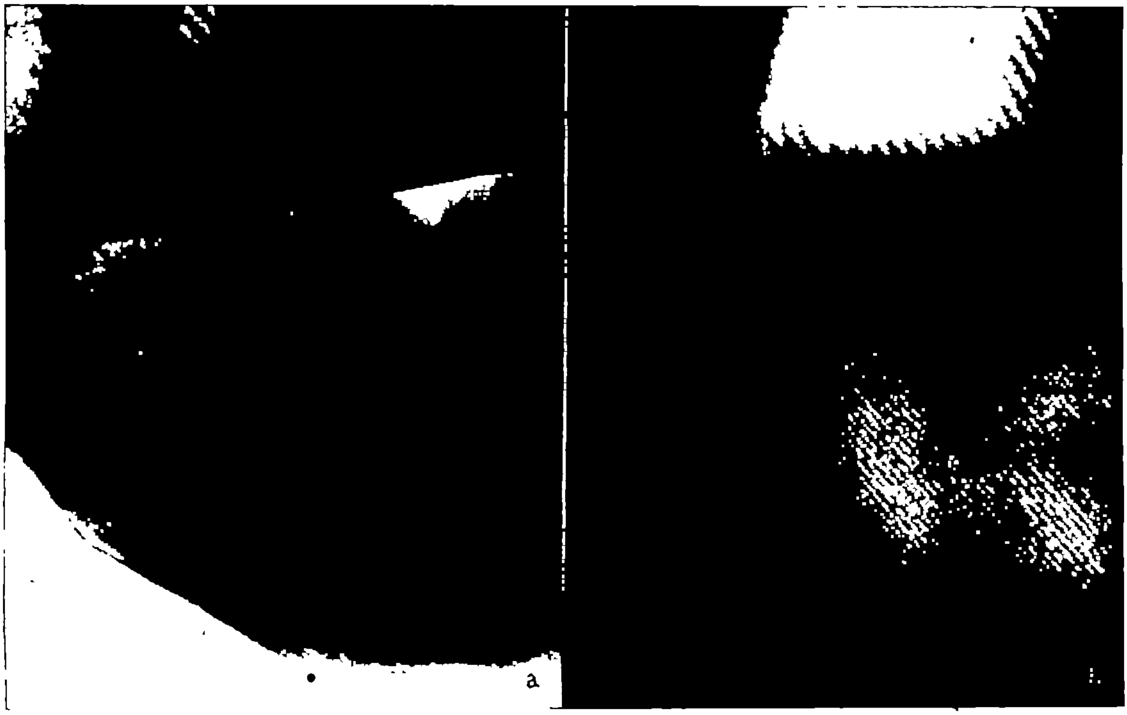

Fig. 4. (*a*) Moiré pattern in the bright field showing fringes of spacing approximately 140 A. (*b*) Moiré pattern in dark field of same area as Fig. 4*a*. As well as the fringes of spacing about 140 A., fringes of spacing about 60 A. can be seen on another crystal. (× 160,000)

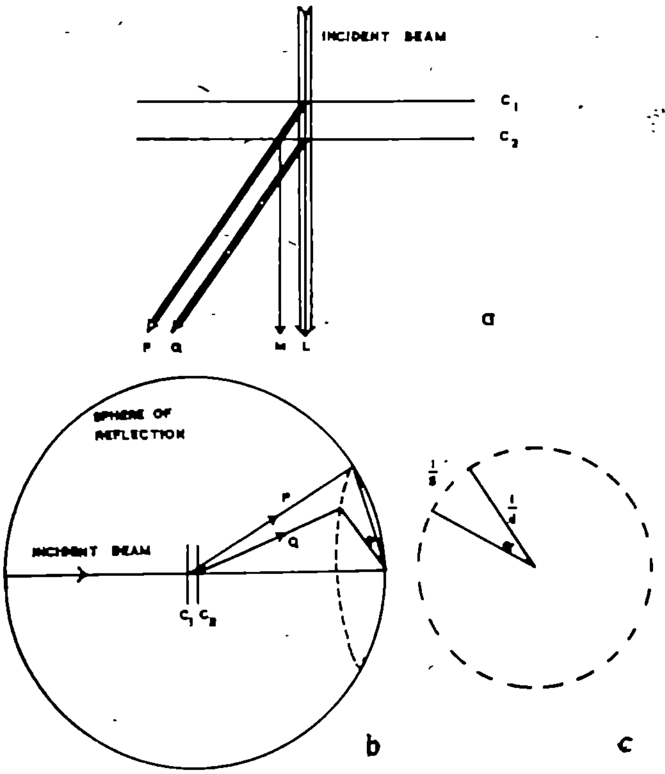

Fig. 5 Formation of fringes in dark field

parallel to the basal plane. The incident electron beam is normal to the basal plane. The beams P and Q combine in the image plane to give fringes of spacing S (cf. Menter[4]) and it is readily seen that in this case also $S = d/\alpha$, where d is the spacing of the planes involved in the diffraction, and that the fringes are perpendicular to the planes producing them.

The angle required to produce the fringes shown in the dark-field photographs 3a and 3b is too small to enable two spots at A and B to be convincingly resolved in the diffraction pattern. At higher orders more than one spot can be seen, but they are too close together for an accurate measurement of their separation to be made. However, the diffraction pattern obtained from two metal crystals shown by Pashley, Menter and Bassett[1] demonstrates that in favourable circumstances each diffraction spot can be resolved.

Frequently fringes were observed when there was no obvious overlapping of two separate crystallites. The fringes with a spacing of approximately 60 A. shown in Fig. 4b using the dark-field technique are a typical example. From his X-ray powder photographs, Pease showed that the crystallite thickness deduced from the breadths of the $(hkil)$ lines was smaller than that deduced from the breadths of the $(000l)$ lines. He inferred that the boron nitride crystallites have packing faults consisting of a displacement of the layers perpendicular to the c-axis. The present results indicate that the fringes observed in many cases arise from a packing fault involving a small angular twist about the c-axis. Many of the micrographs (for example, Fig. 1) show fringes with various types of discontinuities which may be interpreted as imperfections in the crystals.

I thank Dr. F. P. Bowden for his interest and advice. Thanks are also due to Dr. D. W. Pashley and Mr. M. Camp for helpful discussions, Mr. R. S. Pease for the boron nitride, Mr. C. K. Jackson for assistance, Acheson Colloids, Ltd., for a research fellowship, and Industrial Distributors, Ltd., for a grant to the laboratory.

PROPERTIES OF HELICORUBIN AND CYTOCHROME *h*

By Dr. JOAN KEILIN
Department of Veterinary Clinical Studies, School of Veterinary Medicine, University of Cambridge

HELICORUBIN, which is an extracellular hæmochromogen found in the red fluid contents of the digestive tract of land snails, was first observed in 1876 by Sorby[1], and its reversible oxidation and reduction *in vitro* as well as some of its spectroscopic properties have been described on the crude material obtained from snails[2]. The pigment has been found to be widely distributed among molluscs, crustaceans and polychætes[3].

Helicorubin and a very similar hæmochromogen found in the digestive gland (hepatopancreas) of the snail *Helix pomatia* have now been purified by methods described in detail elsewhere[4]. The intracellular hæmochromogen from the digestive gland has been provisionally named 'cytochrome *h*', since it was found to differ in certain respects from helicorubin and to have several properties in common with the cytochromes belonging to the *b* and *c* groups.

Purified helicorubin and cytochrome *h* were found to be homogeneous on moving-boundary electrophoresis, and their electrophoretic mobilities showed that both hæmoproteins are acidic, their isoelectric points lying below pH 4·3. Sedimentation studies in the ultracentrifuge showed in each case only one symmetrical, slowly sedimenting boundary. From the sedimentation and diffusion constants their molecular weights were found to be about 18,000. Their colours and absorption spectra in the oxidized and reduced forms are those of typical parahæmatin and hæmochromogen compounds respectively[4], the α-band of reduced helicorubin lying at 561·5 mμ and that of cytochrome *h* at 556 mμ.

Separation of the Prosthetic Group from the Protein

The prosthetic group of helicorubin can easily be separated from its protein by treatment with acetone containing 0·1–1 per cent v/v of concentrated hydrochloric acid and at room temperature the reaction is complete within a few minutes. The almost colourless precipitate of denatured protein is centrifuged off, leaving a clear peach-coloured acetone solution of acid hæmatin which is soluble in ether. On the addition of sodium hydroxide and sodium dithionite to the acid hæmatin, its absorption spectrum is replaced by that of the dihydroxyhæm compound[5]. The latter, in the presence of pyridine, gives a typical pyridine hæmochromogen with an absorption spectrum indistinguishable from that of pyridine hæmochromogen obtained from crystalline protohæmin, the positions of the two bands in the visible region being: α, 558 mμ; β, 528 mμ. These findings are in agreement with some of the results recorded by Dhéré, Vegezzi, Anson and Mirsky[2].

Although in cytochrome *h* the prosthetic group is more firmly linked to the protein than in helicorubin, it can nevertheless be split off by treating it with acetone containing 4 per cent v/v of concentrated hydrochloric acid giving a clear acetone solution of ether-soluble acid hæmatin, or by pretreating it with aqueous 0·5 *N* hydrochloric acid followed by the addition of acid acetone. However, the α-band of the pyridine hæmochromogen prepared from this hæmatin lies at 555 mμ, that is, 3 mμ nearer the blue end of the spectrum than the α-band of pyridine protohæmochromogen.

Considering that the prosthetic group of cytochrome *h* is much more firmly linked to the protein than in other hæmoproteins with the exception of the *c* group of cytochromes, that it can nevertheless be separated from its protein by acid–acetone treatment and that the absorption bands of its pyridine hæmochromogen lie nearer the blue end of the spectrum, one may suggest that it is a somewhat modified protohæmatin not necessarily deprived of both its unsaturated vinyl groups in positions 2 and 4 of the porphyrin. Were these groups joined to the two cysteine residues of the protein by thioether linkages as was shown[6] for cytochrome *c*, or condensed in any other way with some other amino-acid residues of the protein, the α-band of the pyridine hæmochromogen given by such a hæm would lie at about 550–551 mμ (that is, close to the α-band of the pyridine hæmochromogen obtained from meso- or copro-hæm[7]) and not at 555 mμ as was found experimentally; neither would the prosthetic group be separated from its protein by acid acetone giving a clear acetone solution of acid hæmatin.

Two suggestions can be offered as to the possible nature of the prosthetic group of cytochrome *h*: (1) it may be a protohæmatin which has undergone a minor change, not yet properly understood, which is known to occur in protohæmatin dissolved in weak alkalis such as sodium carbonate or phosphate after standing for a day or two[8]; or (2) it may be a protohæmatin in which only one of the vinyl side-chains is linked to an amino-acid residue of the protein but can nevertheless be split off by comparatively mild treatment without regaining the double bond. However, the solution of this interesting problem remains open for further investigation, which would require much more material than has so far been available for this purpose.

Oxidation and Reduction

Helicorubin and cytochrome *h* are both readily reduced by sodium dithionite, sodium borohydride, ferrous sulphate, ferrous oxalate, ascorbic acid, cysteine and glutathione but not by potassium ferrocyanide. Both hæmoproteins in the reduced (ferrous) state are readily oxidized by potassium ferricyanide, hydrogen peroxide and ferricytochrome *c*. Preliminary estimation (Hill, R., and Keilin, J., unpublished observations) of the oxido-reduction potential of helicorubin and cytochrome *h* using naphthoquinone as buffer at *p*H 7 and 24° have shown $E_0' = +0{\cdot}20$ V. for both hæmoproteins, a value which occupies an intermediate position between those of cytochrome *b* ($E_0' = -0{\cdot}05$ V. at *p*H 7·4)[9] and cytochrome *c* ($E_0' = +0{\cdot}256$ V. at *p*H 6)[10], though lying nearer that of cytochrome *c*.

The old observations by Sorby, Krukenberg and MacMunn (see refs. 1, 2) that, in slightly acid gastro-intestinal fluid or 'bile', helicorubin is oxidizable in the presence of air were confirmed by Dhéré and Vegezzi (see ref. 2), who also suggested that its reduction on making the 'bile' alkaline is due to the appearance of reducing substances. These results were confirmed in the course of the present investigation, since it was found that 'bile' made alkaline reduces not only helicorubin but also purified cytochrome *c* added to it. Even highly purified helicorubin preparations (freeze-dried after stage III of the purification[4]) when treated with *N* sodium hydroxide undergo partial reduction, which is probably due to the presence of carbohydrates in these preparations.

The reactions of helicorubin and cytochrome *h* with oxygen were studied over a wide range of *p*H (2–14), and it was found that in acid solutions they become autoxidizable at *p*H 6, the reaction becoming rapid below *p*H 5·5, whereas in alkaline solution they do not undergo autoxidation even when kept in a solution of *N* sodium hydroxide. Cytochrome *h* tested similarly was shown to become autoxidizable at approximately the same *p*H as helicorubin.

Reactions of Helicorubin and Cytochrome *h* in Biological Systems

Both helicorubin and cytochrome *h* react with the components of the respiratory chain of the heart muscle preparation, being reduced on the addition of sodium succinate or of reduced diphosphopyridine nucleotide and oxidized by the cytochrome oxidase system. The reduction of these hæmoproteins may be followed spectrophotometrically as described[11] for cytochrome *c*; but the concentration of the heart muscle preparation must be much higher than for cytochrome *c* and cyanide must be omitted from the reaction mixture, since in its presence reduction is incomplete. Considering that these hæmoproteins do not react with cyanide, as will be shown later, it is possible that a factor sensitive to cyanide, present in a small amount in the heart muscle preparation, is involved in the respiratory chain linking the dehydrogenase systems with these hæmoproteins. The reduction of helicorubin and cytochrome *h* by these systems, like that of cytochrome *c*, is inhibited by urethane and antimycin A. The oxidation of helicorubin and cytochrome *h* by the cytochrome oxidase system of a cytochrome *c*-deficient heart-muscle preparation[12] was studied manometrically and spectroscopically using ascorbic acid as hydrogen donor. These experiments showed that the addition of exogenous cytochrome *c* is essential for the oxidation of helicorubin and cytochrome *h* by cytochrome oxidase, and the reaction was found to be inhibited by cyanide and azide. The oxidation of reduced helicorubin and cytochrome *h* by oxidized cytochrome *c* can be observed spectroscopically in clear solutions of these hæmoproteins.

Accessibility of Hæmatin Iron to Ligands

Since helicorubin and cytochrome *h*, like cytochrome *c*, are naturally occurring hæmochromogen compounds, in each the iron atom of the prosthetic group is linked in positions 5 and 6 with two nitrogenous groups of the protein, one on each side of the flat molecule of the hæmatin (Fe^{3+}) or hæm (Fe^{2+}). The hæmatin or hæm prosthetic group of these hæmoproteins must therefore lie within a fold of the corresponding protein.

It has been shown that oxidized cytochrome *c* in solution combines reversibly with cyanide[13] and nitric oxide[14] within the physiological range of *p*H. Under similar conditions, reduced cytochrome *c* is not autoxidizable and combines neither with carbon monoxide nor with cyanide. Only below *p*H 4 or above *p*H 13 does it become autoxidizable and combine with carbon monoxide[14-16], while at *p*H 13 it forms a compound with cyanide[16]. This shows that the divalent iron of cytochrome *c* becomes accessible to ligands only when the bonds uniting its iron atom to the protein, and probably also some of the bonds linking the peptide chains within the protein folds, are loosened by treatment with acid or alkali. This process appears to be reversible provided the treatment is not too prolonged.

Oxidized helicorubin and cytochrome *h* do not combine with ligands such as cyanide and nitric oxide within the physiological range of *p*H. Outside this range, only the formation of a nitric oxide compound was followed spectroscopically and the reaction was found to take place at *p*H 2–3.

Reduced helicorubin and cytochrome *h* failed to react with carbon monoxide and cyanide even on standing in *N* sodium hydroxide solution for several hours; but when these hæmoproteins were treated with acids at *p*H 2 or 1·6 and then neutralized or made alkaline, they were found to combine with carbon monoxide and cyanide, forming compounds with characteristic absorption spectra. The absorption bands of these helicorubin compounds lie in the same positions as those of the same compounds obtained from protohæm, whereas the absorption bands of the corresponding derivatives of cytochrome *h* lie 2 or 3 mμ nearer the blue end of the spectrum. It is important to note that the above treatment, which makes the iron of these hæmoproteins accessible to carbon monoxide, cyanide and nitric oxide, causes irreversible denaturation of their proteins.

Properties of Helicorubin and Cytochrome *h* compared with those of Cytochrome *c*

Helicorubin and cytochrome *h* have several properties in common with a typical cytochrome *c* such as that isolated from baker's yeast or from horse heart muscle. These are: (1) a low molecular weight; (2) thermostability; (3) stability within a very wide range of *p*H (3–14); (4) the inaccessibility of their divalent iron to ligands; (5) the inhibition by antimycin A of their reduction by a heart muscle preparation containing sodium succinate or reduced diphosphopyridine nucleotide; and (6) the inhibition by cyanide of their oxidation by the cytochrome oxidase system.

They differ from cytochrome *c* in the following respects:

(1) In the reduced state their absorption spectra bear a greater resemblance to that of cytochrome *b* than to that of cytochrome *c*.

(2) Their isoelectric points lie below *p*H 4·3, whereas in cytochrome *c* it is above *p*H 10. In this respect they resemble some of the acidic cytochromes of the *c* group which have been isolated from bacteria[17,18].

(3) Their iron, both in the divalent and tervalent states, is less accessible to ligands (CO, CN′ and NO) than that of cytochrome *c*.

(4) Their oxido-reduction potentials lie about 66 mV. below that of cytochrome *c*.

(5) They are not autoxidizable in alkaline solutions (even in 2 *N* sodium hydroxide), but on the acid side autoxidation begins at *p*H 6, whereas cytochrome *c* only becomes autoxidizable below *p*H 4 and above *p*H 12.

(6) The prosthetic groups of helicorubin and cytochrome *h*, unlike that of cytochrome *c*, can be separated from their respective proteins by acid acetone, giving clear solutions of ether-soluble acid hæmatins. But whereas in helicorubin the prosthetic group is indistinguishable from protohæmatin, in cytochrome *h* it is a somewhat modified protohæmatin in which one of the vinyl groups is probably replaced by a saturated side-chain.

(7) The fact that the autoxidation of helicorubin and cytochrome *h* occurs at a *p*H when their iron is still inaccessible to ligands suggests that the autoxidation does not necessarily imply a direct reaction between the divalent iron and oxygen, but may be brought about in the same way as the oxidation of these hæmoproteins by ferricyanide or by oxidized cytochrome *c*.

This work has been carried out while in receipt of research grants from the Agricultural Research Council and the Wellcome Trust.

Theories of Crystal Elasticity

From the time of the publication of the "Lehrbuch der Kristallphysik"[1] until 1951 there was no challenge to the classical theory of the elastic properties of crystals. At the Solvay Conference of that year, Laval[2] published an account of a theory which rejected some of the fundamental assumptions made in classical theory. Further work leading to the same conclusions was published later by Le Corre[3], Viswanathan[4], Raman[5] and Krishnamurti[6]. In non-mathematical language the difference between the old and new theories may be expressed as follows. On the classical theory, the equilibrium of a cube within a body at rest, which is subjected to any given set of mechanical stresses, is maintained solely by the forces acting normally or tangentially to its surfaces. If one edge of the cube is supposed vertical then tangential forces act on the vertical faces and, in equilibrium, the couples due to the tangential shear stresses acting on these faces just balance. The new theory denies the adequacy of this statement and asserts that 'volume-couples' can exist which must be balanced by the difference between the couples which were assumed to be equal and opposite in the old theory. In more formal language, the old theory asserts that the stress tensor is symmetric while the new theory asserts that it is in general non-symmetric. A corresponding difference exists in the treatment of the deformation experienced by the cube. The old theory assumes that all net rotations of the whole body may be regarded as irrelevant, so far as its elastic deformation is concerned. The new theory denies this and asserts that the deformation can only be adequately described by taking into account any net rotation which may be caused by the stresses. More formally, the old theory assumes a symmetric and the new theory a non-symmetric tensor for the strain. One of the consequences of the new theory is that the number of elastic constants is increased, for example, in the triclinic system from twenty-one on Voigt's theory to forty-five on the new theory.

To illustrate how volume couples can arise, a working model has been constructed which is in fact a model of one unit cell of the hexagonal form of selenium (Fig. 1). The four vertical rods have a triangular cross-section and are twisted about their lengths. Plates with a triangular hole fit over these rods and are separated by springs. (In Fig. 1 only one vertical rod is shown with its springs in place.) To each plate is attached a short horizontal rod in the appropriate direction, and a ball representing a selenium atom is supported by this rod. The whole unit cell can be compressed in a vertical direction by means of a frame. When this is done, the balls rotate about the vertical rods by an amount proportional to their distance above the base. How far can this model represent the state of affairs in the actual crystal?

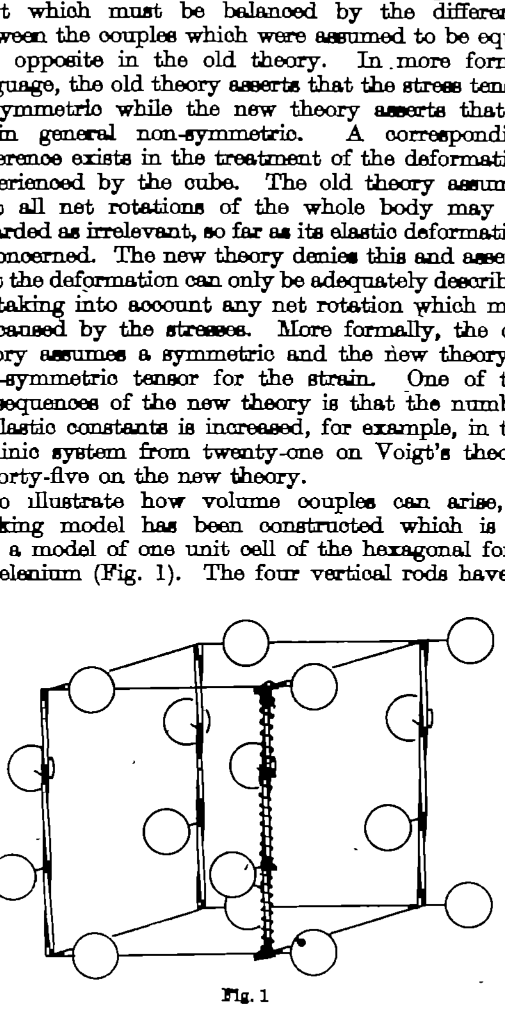

Fig. 1

The shortest bonds between selenium atoms form spiral chains parallel to the c-axis. The bonds between atoms in neighbouring spirals are longer and hence weaker than those within a given spiral. It is, therefore, not inconsistent with the symmetry, or with the arrangement of the atoms, for them to move in the manner indicated by the model. If such a rotation of the spiral chains tended to occur it would be resisted by the forces acting between the atoms in neighbouring spirals. In this way each spiral would be the origin of a couple and all these couples taken together would form a volume-couple of the kind assumed in the new theory.

If the spiral nature of the atomic distribution is responsible for the breakdown of the classical assumptions, then it is possible to establish in what classes of symmetry new effects might be observed. A centre of symmetry necessitates the presence of parallel spirals of opposite hands, and therefore it would not be expected that any centro-symmetric class would require the new theory. A plane of symmetry also converts a right-handed into a left-handed spiral but, except when the plane is parallel or perpendicular to the axis of the spiral, the rotatory effects are not mutually destructive. Thus, in addition to the eleven classes having only axes of symmetry, there are certain others, namely, m, mm, $\bar{4}$ and $\bar{4}2m$, in which the symmetry elements produce not more than two non-parallel groups of spirals of opposite hands. In these fifteen classes the new theory could apply if the spiral atomic arrangements are the determining cause. As an example of a crystal of class $\bar{4}2m$, ammonium dihydrogen phosphate ($(NH_4)H_2PO_4$) may be quoted. The structure of this crystal has PO_4 tetrahedra linked by hydrogen atoms in such a way as to build up spirals of atomic bonds —O—P—O—H—O—P—O—H—O— running parallel to the two-fold axes.

Experimental tests of the new theory have been carried out in two ways. Crystals of ammonium dihydrogen phosphate, when subjected to supersonic vibration and examined in a beam of light parallel to the a-axis, give a Bergmann–Schaefer diffraction pattern which shows that the mechanical transverse wave having a vibration direction lying in the bc-plane has a different velocity according to whether it vibrates along b or along c. The difference[3] is 17 per cent and far exceeds the experimental error. According to the old theory these velocities should be the same. Quartz crystals[7] examined by the same technique also afford support for the new theory. Another test is afforded by the piezoelectricity of quartz. According to the old theory (and the classical experiments) no charge can be liberated on the basal plane by any application of stress. Le Corre[8] has shown that when a torque is applied about the optic axis, a charge is developed on the plane perpendicular to that axis. All the above experiments which have supported the new theory refer to crystals belonging to the classes of symmetry already mentioned.

Thus we believe that the classical theory of crystal elasticity is not applicable to crystals of all classes of symmetry and that some new theory would be applicable to the eleven enantiomorphous classes and also to classes *m*, *mm*, $\bar{4}$ and $\bar{4}2m$.

One of us (N. J.) gratefully acknowledges his indebtedness to the British Council for a research scholarship.

Direct Structure Determination by Optical-Transform Methods

The optical-transform methods[1] for solving crystal structures are obviously of greatest use in dealing with chemical molecules the main outlines of which are known. It is interesting, however, to see whether they might be used for determining a crystal structure directly without any chemical information other than that of the unit-cell contents.

The following is a brief account of a structure investigated in this way; it is a simple example chosen specifically because it seemed to provide reasonable conditions for the operation of optical methods.

The substance crystallizes in the space group $P2_12_12_1$; the unit cell has dimensions $a = 17 \cdot 11$, $b = 3 \cdot 80$ and $c = 10 \cdot 67$ A. and contains four molecules of $C_7O_2NH_7$. The work to be described has been carried out entirely on the (010) projection, which belongs to the plane group *pgg*.

The *h0l* section of the weighted reciprocal lattice is reproduced in Fig. 1; it shows pronounced groups of strong reflexions at about 0·8 A.$^{-1}$ from the origin, arranged in a way that indicates the existence in the structure of a group of atoms similar to a benzene ring, the orientation and size of which can readily be deduced[1]. In addition, it shows a rectangular arrangement of strong reflexions about the origin which is long in the direction of a^*, and therefore implies a molecule which is long in a direction parallel to *c*.

To find the positions of the four rings in the unit cell, Taylor's[2] method was applied to those reflexions that lay on the strong parts of the transform of the single ring but which were, nevertheless, of small or zero intensity. An optical transform of the arrangement thus found was prepared and indicated reasonable agreement over much of the weighted reciprocal lattice section.

Signs were determined optically[3], and a Fourier synthesis calculated. This showed, of course, the ring which had been postulated, but, in addition,

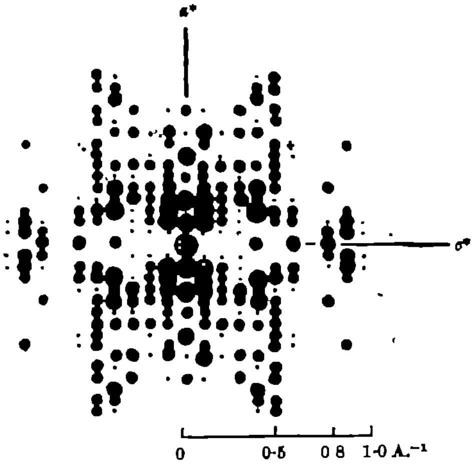

Fig. 1. The *h0l* section of the weighted reciprocal lattice

several smaller peaks appeared. These were assumed to give possible positions of some of the remaining five atoms. Of a number of possibilities tested optically, the one which gave best agreement was taken as a basis for a further sign determination and Fourier synthesis. The choice of possible arrangements was also guided by the information that the molecule was long in the direction parallel to *c*. Continuation of these processes led to a molecule of eleven atoms, but the agreement residual for it could not be reduced to less than 0·45. It appeared, then, that Taylor's method, when applied to only about half the molecule, did not give reliable results. Nevertheless, it was hoped that the molecule found was substantially correct, and that application to the complete molecule would be more successful. One important difficulty in this problem is that the four rings in the projection are nearly parallel and thus add a pseudo mirror-plane which reduces the chance of obtaining a solution by the method.

To overcome this difficulty, a more quantitative form of the method has been devised. It is based upon the principle of the structure-factor graph[4]. A map of a function representing the combined discrepancies between observed and calculated intensities for a few chosen reflexions is prepared;

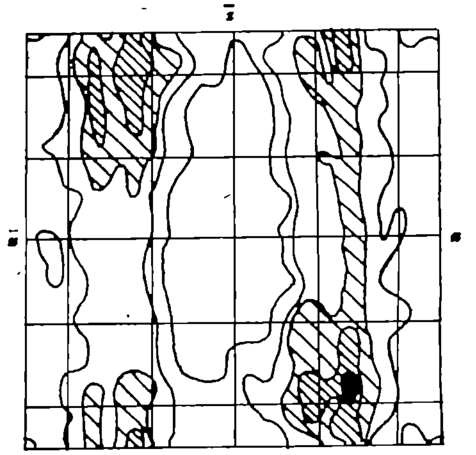

Fig. 2. Graph giving the position of the molecule in the unit cell, which is denoted by the small black region

its minimum point indicates the position of the molecule in the unit cell. The calculations were carried out by means of Beevers–Lipson strips[5], and the results are shown in Fig. 2. It will be seen that a pronounced minimum exists, and this was taken as giving the position of the molecule.

This position represents a shift of about 0·5 A. in the z-direction from that found by considering the rings alone. It gave a residual of 0·30 which later refinement has reduced to 0·15. The oxygen and nitrogen peaks are clearly distinguished, by their size on a Fourier synthesis, from the carbon atoms, and these results are in agreement with the configuration of the molecule obtained independently from chemical evidence. The structure must, therefore, be essentially correct.

Further details of the work will be published elsewhere.

An Experimental Proton Linear Accelerator using a Helical Waveguide

A previous communication[1] proposed the use of a helical slow-wave structure to accelerate protons up to 20 MeV. An experimental section of this type of accelerator has now been constructed at this Laboratory.

The helix structure consisted of a wire helix wound on a glass tube which was evacuated to allow the proton beam to pass along the axis. Outside the tube a pressure of 150 lb./sq. in. was maintained to prevent radio-frequency breakdown between turns of the helix and to assist in cooling. Cooling is important, since in some circumstances the mean dissipation may be as much as 600 watts per metre. The helix radius was 1 cm. and the pitch varied from 4 mm. at the input to 4·6 mm. at the output end to accelerate particles from 2·5 to 4 MeV. This acceleration was obtained in a 1-metre length for a peak power flux of 500 kW. at 300 Mc./s. with a phase stable position of 30°. No attempt was made to counteract the inherent defocusing effect of the radio-frequency accelerating field over the 1-metre length, and it was accepted that some of the beam may be lost into the walls of the beam tube.

Protons were injected into the accelerator by an electrostatic generator[2], the beam being pulsed before injection to reduce wall-charging effects in the accelerator tube. The energy of the beam after acceleration was measured by magnetic deflexion, and the current to the beam-collecting electrode was measured by the rise of voltage across the electrode capacitance, amplified in a screened head amplifier and displayed on an oscilloscope. The accelerator was operated under travelling-wave conditions without external feedback, the full 500 kW. of radio-frequency power at 300 Mc./s. being provided by an oscillator specifically designed for this purpose. The oscillator was driven from a radar modulator modified to give a 6-μsec. pulse. The high-frequency power at the input and output of the helix was monitored, providing a constant check on the transmission losses.

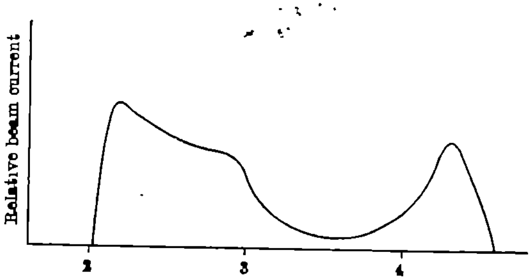

Fig. 1. Energy spectrum for 500-kW. radio-frequency power flux and 2·5-MeV. injection energy

The measurements which are of primary interest are the energy spectrum under optimum conditions, and the relative magnitude of the accelerated beam. Fig. 1 shows the energy spectrum for the design values of power flux and beam energy input, which proved to be near optimum. The curve represents the average of a large number of readings necessitated by fluctuations of beam current, presumably arising from wall-charging inside the tube supporting the helix. The peak in the spectrum at 4·3 MeV. was higher than expected from the design figures, but cold measurements of phase velocity indicated a final velocity corresponding to nearly 4·3 MeV. The spread of energy at the accelerated peak was consistent with the theoretically predicted value of ± 5 per cent, and magnetic analyser resolution of 0·2 MeV. The beam current in the range 4·3 MeV. ± 5 per cent represented 20 per cent of the total current in the spectrum. This result compares reasonably with the design value of 25 per cent for a 90° acceptance angle, which suggests that only a small proportion of the beam is lost by defocusing, even though a large (5 mm. diameter) beam was used. The total current in the spectrum, however, represents only 15 per cent of the input beam current, and it is thought that this loss of current is due to deflexion of the beam by charges on the glass walls of the tube supporting the helix.

The results so far obtained with the helix accelerator indicate that it functions in principle in accordance with design. To increase the relative accelerated beam current, however, it would be necessary to surmount the problem of preventing wall-charging and, for a higher-energy accelerator, preventing defocusing.

We wish to thank Mr. R. Bailey for his part in this work and Dr. T. E. Allibone for permission to publish this communication.

Diurnal Variation in the Occurrence of 'Dawn Chorus'

In the audio-frequency range, a phenomenon called 'dawn chorus', which is characterized by a multitude of rising tones, is frequently observed. Other investigators[1,2] have noted that this phenomenon exhibits a pronounced diurnal variation of intensity, with the maximum occurring during the early morning hours, and the name 'dawn chorus' has been derived on this basis. The observations of 'dawn chorus' reported here were made between January 1 and July 2, 1956, at College, Alaska, with equipment sensitive to frequencies between 1 to 10 kc./s. During this interval, the equipment was in operation on 116 days. 'Dawn chorus' was found to be present in 224 of the 2,784 one-minute hourly observing periods. The diurnal variation in the frequency of occurrence of 'dawn chorus' is illustrated in Fig. 1, which represents a histogram of the number of times 'dawn chorus' was found to be present during the one-minute recording interval for each of the twenty-four hours of the day.

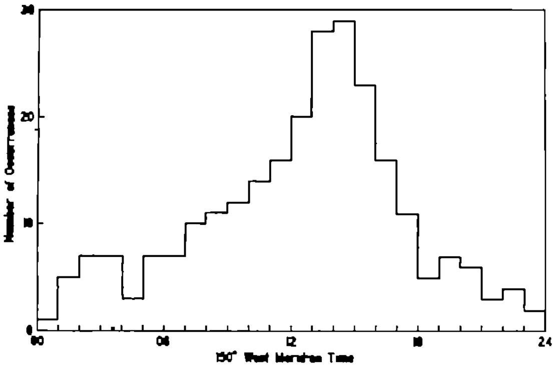

Fig. 1. Diurnal variation in the occurrence of 'dawn chorus' at College, Alaska

The main feature shown by the histogram is that the time of maximum occurrence of 'dawn chorus' at College is at 1400 hr. local time, in contrast to the morning hour maximum noted by other observers. Since College is situated in a high geomagnetic latitude whereas the earlier observations were made at lower latitudes, one is led to inquire if the difference in the local time of maximum varies systematically with latitude. In order to test this hypothesis, the observations of 'dawn chorus' at College for the first half of the year 1956 have been compared with those obtained during the same period at four other stations. The local times of the daily maximum in the occurrence of 'dawn chorus' for the five stations are listed in Table 1 and plotted against geomagnetic latitude in Fig. 2. A straight line has been fitted to the points of that figure. Storey[1] gives 0600 as the time of maximum for Cambridge (geomagnetic latitude 55° N.), and the corresponding point (*CA*) has been included in Fig. 2 for comparison.

Table 1

Station	Symbol	Geo-magnetic latitude	Local time of maxi-mum	Mean local magnetic noon
College, Alaska	*CO*	65° N	1400	1350
Hanover, New Hampshire	*HA*	55° N	0700	1200
Washington, D.C.	*WA*	50° N	0500	1215
Wellington, New Zealand	*WE*	45° S	0200	1115
Dunedin, New Zealand	*DU*	50° S	0430	1120

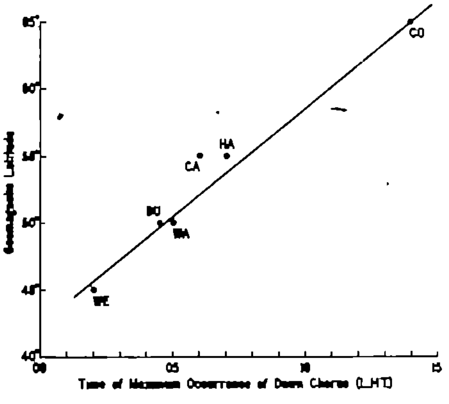

Fig. 2. Local time of maximum in the diurnal variation of occurrence of 'dawn chorus' as a function of geomagnetic latitude

Although the number of points is limited, the observations nevertheless suggest that the time of the diurnal maximum in the occurrence of 'dawn chorus' is related to geomagnetic latitude.

In view of the fact that the daily maximum of 'dawn chorus' does not, in general, occur at dawn, it is suggested that it be referred to simply as 'chorus'.

The observations from the stations in New Zealand and the United States were obtained by interchange, and I wish to acknowledge the co-operation of Drs. G. M. Allcock, H. E. Dinger, L. H. Martin and M. G. Morgan. I am also indebted to Dr. L. Owren for assistance in the preparation of the manuscript. The work reported here was supported by the U.S. Air Force Cambridge Research Center, under contract No. *AF* 19(604)-1859.

Band Spectrum of Gallium Hydride and Gallium Deuteride

I HAVE observed and measured some faint absorption bands in the spectra of gallium hydride and deuteride. The bands are composed of single *P*, *R* and *Q* branches belonging to a $(\Pi - \Sigma)$ electron transition. The branches are degraded to the violet, and consist of sharp and wide-spaced lines.

The spectrograms were taken with a high resolving power immersion spectrograph[1]. A quartz tube with an effective absorption length of 120 cm. was used as the absorption cell. The tube was heated by means of an electric furnace to a temperature of about 1,200° C., the pressure of hydrogen and deuterium being 1 atm. The following constants were calculated for (0–0) bands:

Gallium hydride		Gallium deuteride	
ν_0 =	17,626·84 cm.$^{-1}$	ν_0 =	17,634·36 cm.$^{-1}$
B_0'' =	6·046 cm.$^{-1}$	B_0'' =	3·088 cm.$^{-1}$
B_{cd}' =	6·518 cm.$^{-1}$	B_{cd}' =	3·337 cm.$^{-1}$
B_{dc}' =	6·536 cm.$^{-1}$	B_{dc}' =	3·340 cm.$^{-1}$
D_0'' =	-356×10^{-6} cm.$^{-1}$	D_0'' =	-84×10^{-6} cm.$^{-1}$
D_{cd}' =	-449×10^{-6} cm.$^{-1}$	D_{cd}' =	-109×10^{-6} cm.$^{-1}$
D_{dc}' =	-468×10^{-6} cm.$^{-1}$	D_{dc}' =	-116×10^{-6} cm.$^{-1}$

Garton[2] has observed some bands at 2160–2400 A. in absorption through gallium vapour in a hydrogen atmosphere. These bands were provisionally ascribed by Garton to the molecule GaH.

Further details of the spectra of gallium hydride and deuteride will appear later in *Arkiv for Fysik*.

Ultra-Violet Absorption Spectra of L-Ascorbic Acid in Aqueous Solutions

In a previous communication[1], it was reported that D-sorbitol enhances the absorption in the ultraviolet by aqueous solutions of L-ascorbic acid. Continuing the work, it appeared that the 'enhanced' values are simply the true values of the ultra-violet absorption of L-ascorbic acid, which hitherto have been measured only occasionally and unsystematically.

As will be seen from Table 1, the values of E(1 per cent, 1 cm.) given in the literature are around 550, with some notable exceptions. Some of the values reported were obtained in the presence of potassium cyanide, which is known to prevent autoxidation of ascorbic acid. However, the highest values, given by Carpeni, were obtained without the addition of cyanide and in anaerobic conditions. The values given in my previous communication were 630 and 550 for the mono-dissociated and non-dissociated forms of L-ascorbic acid. In the presence of D-sorbitol, the respective values were 916 and 676. Pursuing the investigation, it was found that ethylenediaminetetra-acetic acid (versene), like D-sorbitol, enhanced the ultra-violet absorption of L-ascorbic acid; this suggested that both substances could act by trapping copper or other metallic ions which have a catalytic effect on the autoxidation of the acid.

Table 1. Values of E(1 per cent, 1 cm.) found in the literature for the ultra-violet absorption bands of the non-dissociated (245 mμ) and the mono-dissociated (265 mμ) form of L-ascorbic acid in aqueous solutions

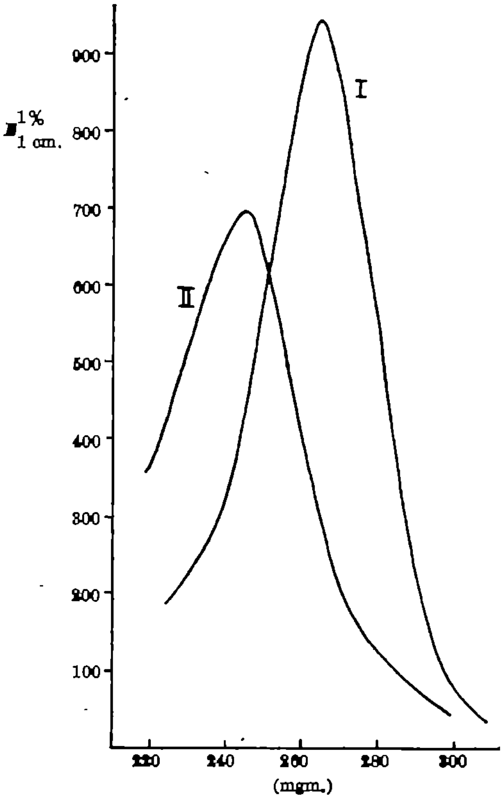

Fig. 1. Ultra-violet absorption of L-ascorbic acid (I) at pH 6·4; (II) at pH 2·0

It was finally found that by working with the purest ascorbic acid, glass-distilled water and complete anaerobiosis (removal of traces of oxygen by bubbling oxygen-free nitrogen through the water before the addition of L-ascorbic acid) the following values were obtained: E(1 per cent, 1 cm.), for the non-dissociated form at 245 mμ (pH 2, with dilute hydrochloric acid), 695; for the mono-dissociated form at 265 mμ (pH 6·4, with phosphate buffer), 940. These values are higher than those given in the literature, except for the value (798) given by Carpeni for the non-dissociated form of L-ascorbic acid. I was unable to obtain so high a figure.

My results were obtained with final concentrations ranging from 0·5 to 1 mol. × 10^{-4}. For the lower concentrations, only by the use of strict anaerobic conditions can the values be prevented from decreasing. I believe that my present values are nearer the real ones than any hitherto reported. A warning may be given in connexion with the measurement of L-ascorbic acid absorption for analytical purposes: anaerobic conditions are essential when no stabilizers are used. When anaerobic conditions are difficult to maintain for technical reasons the use of appropriate stabilizers, and among them D-sorbitol as reported, is recommended.

Fig. 1 represents the ultra-violet absorption of aqueous solutions of L-ascorbic acid at acid and neutral pH values.

Hexagonal Chromium Crystals from Fused Electrolytes

The meaning of the hexagonal structure sometimes observed in chromium electroplates has been the subject of considerable study. The present communication is to record some observations on chromium produced by electro-refining in fused-salt baths. The particular bath used in the production of the chromium described here consisted of sodium chloride, chromium chlorides, and dissolved metallic sodium at 800° C. The cathode deposit consisted of a layer of fine crystals in salt and coarse idiomorphic chromium crystals attached to them.

The coarse crystals were in the form of hexagonal plates and rods as shown in Fig. 1. Fig. 2 shows some of the rods bent to show their ductility. Both pictures are at about twice natural size. X-ray examination shows the plates to be body-centred cubic, so that they are pseudomorphs after the hexagonal form.

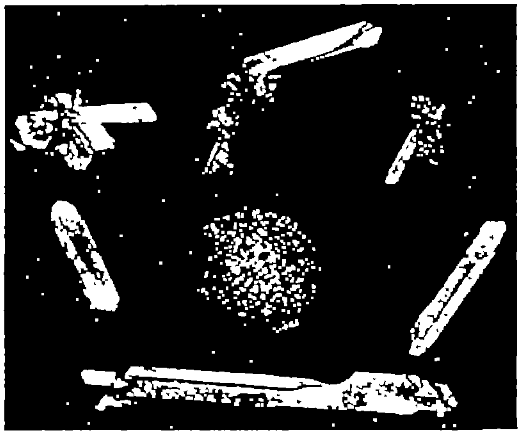

Fig. 1

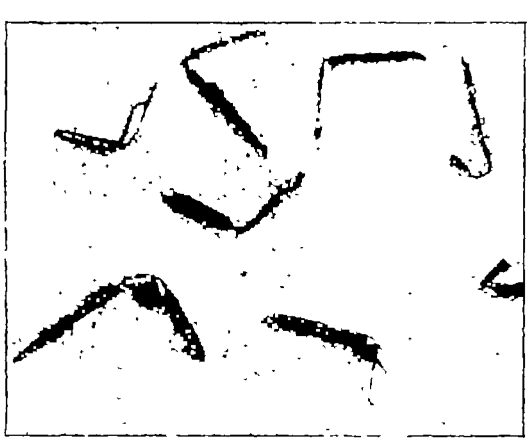

Fig. 2

We regard it as improbable that the hexagonal form is stable at 800° C., but think rather that it represents formation of an unstable modification under the particular conditions. The crystals have a density of 6·9, and a hardness of about 130 DPH.

The layer of fine crystals formed in the salt layer has the lowest electrical resistance reported for chromium, namely, 3·6 microhms/cm.

A Performance Index for Gas Chromatographic Columns

J. Friend and E. Watson have suggested that if an adequate 'performance index' could be defined for gas chromatographic columns, a much-needed clarification could be achieved in the interchange of data among experimenters.

A theoretical study of gas chromatographic columns has indicated that the following expression is reasonably invariant under a large range of conditions, and has other properties which commend it as a performance index:

$$\frac{\Delta t^4}{t^3\left(t-\frac{3}{4}t_a\right)}\cdot(t_a\,\Delta p)$$

where Δt is width of 'band' at mid-height; t_a is time interval between injection and centre of 'air peak'; t is time interval between injection and centre of band; and Δp is pressure drop across column; all times are in seconds, Δp in dynes cm.$^{-2}$.

The theoretical basis for the expression given above, the smallness of which constitutes the desirable property, is too lengthy to give here, but its several properties will be mentioned briefly.

(1) When the column is operated at the optimum flow-rate for band separations, the performance index constitutes a parameter depending essentially upon the packing material of the column; it is invariant with the column diameter and length, and to a large extent with the proportion of oil in the substrate of a gas–liquid partition column.

(2) If written as follows:

$$\text{Performance index} = \left(\frac{\Delta t}{t-t_a}\right)^4\times\frac{(t-t_a)^4 t_a}{t^4\left(t-\frac{3}{4}t_a\right)}\cdot(t\,\Delta p)$$

the first term of the expression is proportional to the fourth power of the relative 'band width', which is analogous to the spectral slit-width of the spectroscopist, and inversely proportional to the resolving power; the second term is a maximum when $t = 4\cdot3\,t_a$, which indicates that, other things being equal, optimum separation of a given pair of components will occur when the capacity of the static phase for these components is a little more than three times the capacity of the mobile phase; and the third term may be considered as the 'price' paid for separation, in terms of the time of waiting required for the elution of the slowest component, and of the pressure drop across the column.

The spectrometrist who works in the far infra-red region and utilizes slit openings which are much larger than the slit-width may note that the price paid for resolution in terms of time of waiting is the same in gas chromatography as in his field of spectrometry. On the other hand, the gas chromatographist has another quantity he can 'trade' for either speed, or resolution, namely, pressure differential across the column.

It should be emphasized that the trading of time and pressure for each other, or for resolution, must be done at the time the column is engineered. Once the column has been designed and installed in the gas chromatographic apparatus, the operating conditions are essentially determined. There is an optimum separation to be obtained for a given pressure-drop and in a given time, and pressure and time may be traded for each other within narrow limits only, without lowering the inherent resolution.

It should also be emphasized that the performance index is fairly characteristic of the column material and column geometry. It serves to guide the engineering of a column, but research is required to find new materials and geometries with the desired smaller performance indexes.

(3) The performance index has the dimension of viscosity in poises, and theoretical considerations indicate that in an ideal column it should be of the order of the carrier-gas viscosity times a large numerical constant; that is, it should be of the order of 0·1 poise. In practice, it has been found to be of the order of 1,000 poises for 'Celite' columns for a large range of oil impregnation, and for a variety of components separated. This very large ratio between the actual and ideal performance indexes constitutes a measure of how much room for improvement there is in basic column design.

Micelle Dimension of Potato Starch

NATIVE starches are, of course, polycrystalline materials, and their submicroscopic structure has been studied using X-ray diffraction procedures by many workers. Nevertheless, the fine structure of native starch granules is still unknown.

We have carried out X-ray diffractometric studies to obtain information on the micelle dimension of starch molecules in connexion with electron microscopic observations of ultra-thin sections of starch granules, which showed an arrangement of very fine micro-granules about 200 A. in diameter[1]. The micelle dimensions of cellulose have been measured in various ways, but for starches no exact experimental results have been reported.

The size of a crystallite of a polycrystalline material can be calculated from the broadening of the diffraction line using Scherrer's equation:

$$D_{(hkl)} = \frac{0\cdot9 \times \lambda}{\beta_{1/2} \times \cos\theta}$$

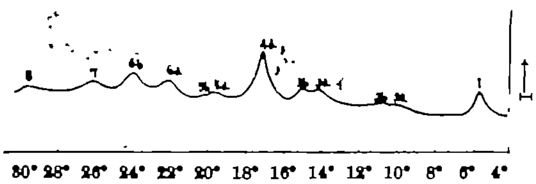

Fig. 1. Whole-line profile of wet potato starch

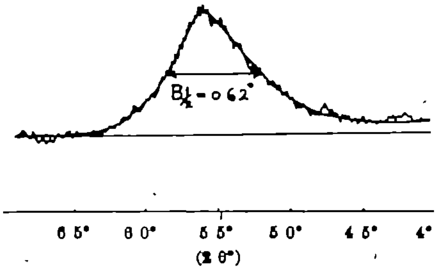

Fig. 2. Line profile of line 1 of wet potato starch

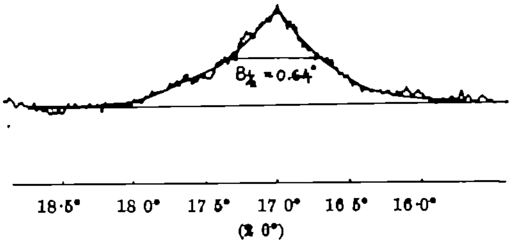

Fig. 3. Line profile of line 4a of wet potato starch

where $D_{(hkl)}$ is a mean dimension and λ, $\beta_{1/2}$ and θ represent the wave-length of X-ray used, the real half-maximum breadth and the Bragg angle respectively[2].

As regards the specimen, potato starch was prepared in the usual manner from potato tubers and stored in a refrigerator as an aqueous suspension. Before use, the suspension was sucked on to a glass filter, washed and the wet specimen was packed into an aluminium frame. A 'Norelco' X-ray diffractometer of the North American Philips Co. was used.

The experimental conditions for obtaining a whole-line profile were as follows: high-tension voltage, 30 kV.; current, 15 m.amp.; scale factor, 4; multiplier, 1; time constant, 8 sec.; divergence slit, 1°; receiving slit, 0·006 in.; scatter slit, 1°; scanning speed, ½° per min.; chart speed, ½ in. per min.; X-rays, nickel-filtered copper radiation.

Some factors were changed when detailed curves for line 1 and line 4a were examined; namely, scale factor, 2; time constant, 16 sec.; divergence slit, ¼°; scatter slit, ¼°; scanning speed, ⅛° per min.; chart speed, ½ in. per min.

A whole-line profile of wet potato starch is shown as Fig. 1. The labelling of the peaks of the curve corresponds to Katz's nomenclature of his Debye–Scherrer rings, and their lattice constants are given in Table 1.

Table 1. LATTICE CONSTANTS OF WET POTATO STARCH

Line	1	2a	2b	3a	3b	4a	5a	5b	6a	6b	7	8
d (in A.)	15·79	8·82	7·89	6·34	5·96	5·215	4·55	4·40	4·04	3·70	3·43	2·89

Figs. 2 and 3 represent detailed curves of line 1 and line *4a*, respectively. Their observed half-maximum line-breadths $(B_{1/2})$, 0·62° and 0·64°, were corrected by Alexander's correction curve[3] and the quartz line (101).

Thus, the pure half-maximum breadths $(\beta_{1/2})$ were deduced as 0·54° for line 1 (100) and 0·56° for line *4a* (020), and the micelle dimensions $D_{(hkl)}$ were calculated as follows:

$$D_{(100)} = 147 \text{ A.}, D_{(020)} = 144 \text{ A.}$$

Thus, $D_{(100)}$ and $D_{(020)}$, that is, the average micelle dimensions for the *a* and *b* directions of Rundle's unit cell of potato starch[4], were estimated to be 147 A. and 144 A., respectively.

The average micelle-length in direction *b*, parallel to the long axis of the molecular chain, corresponds to the length of 28 glucose residues and agrees fairly well with the average end-chain-length of potato amylopectin[5] (27 glucose residues) and also with the average chain-length of potato amylo-dextrin[6] (25 glucose residues), which was prepared by cold acid treatment of raw potato starch and was believed to constitute the crystalline regions of the starch granules.

The average micelle dimension for the *c*-direction of Rundle's unit cell could not be obtained. But this value represents the micelle breadth perpendicular to the long axis of the molecular chain, and it might not be very large.

Therefore, the crystalline part of native wet potato starch may be considered to be a sphere or a bunch of about 145 A. in diameter.

We are grateful to Prof. I. Nitta and members of his laboratory for their valuable advice.

Reaction of Globin with Hæmin in Interfacial Films

RECENTLY, we reported[1] that Π, the maximum pressure of bovine globin in the *p*-xylene/water interface, was approximately twice as high as that of bovine oxyhæmoglobin, and that addition of hæmin lowered the high interfacial pressure of globin. This surprising phenomenon was investigated more thoroughly, as described below.

The interfacial tension was measured by the ring method as described earlier (ref. 1, p. 54). The lower layer was formed by 20 ml. of 0·06 *M*-glycine buffer *p*H 10, containing 0·05 per cent of native bovine globin prepared according to Anson and Mirsky[2]. Increasing amounts of a 0·1 per cent solution of protohæmin chloride in the same buffer solution were added to the globin solution and the interfacial tension measured after stirring the aqueous layer. In control experiments protohæmin was replaced by protoporphyrin, and globin by bovine γ-globulin (Armour).

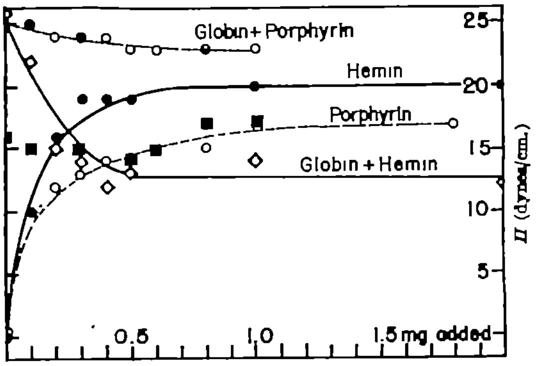

Fig. 1. The abscissa shows the amount of protohæmin or protoporphyrin added to the glycine buffer solution which formed the lower layer. The two ascending curves show the results obtained with protein-free buffer solution, the descending curves the results obtained with 10 mgm. of bovine globin. The black squares indicate values obtained on the addition of protohæmin to a buffer solution containing 10 mgm. of bovine γ-globulin

The interfacial tension γ_i was calculated from the maximum pull by means of the correction factors of Zuidema and Waters[3]. The maximum film pressure, Π, is obtained by deducting γ_i from γ_0, the interfacial tension of the system buffer solution/*p*-xylene (ref. 1, p. 54).

Fig. 1 demonstrates that the amount of hæmin required to lower the interfacial pressure of 10 mgm. of globin to its minimum is 4–5 per cent of the weight of the globin. This is very close to the percentage of hæm in hæmoglobin. Fig. 1 also shows that the globin–hæmin interaction is quite specific; the high interfacial pressure of globin is very little affected by the addition of protoporphyrin, nor is the interfacial pressure of bovine γ-globulin lowered by protohæmin. Fig. 1 also shows that the interfacial pressure increases considerably when hæmin or porphyrin is added to the protein-free buffer solution.

Results identical with those recorded in Fig. 1 were obtained when bovine globin was replaced by native globin of man, rat or rabbit. In all these species the maximum interfacial pressure of globin at *p*H 10 was 22–25 dynes/cm. Reduced hæmoglobin, produced by adding 1 mgm. of sodium dithionite to the aqueous layer, had the same interfacial pressure as the corresponding oxyhæmoglobin. Similar but smaller differences between globin and oxyhæmoglobin were observed in the system water/bromobenzene where the organic solvent forms the lower layer. In the air/water interface the differences in Π were only 2–3 dynes/cm.

Since the globins used in these experiments were native and able to form oxyhæmoglobin on addition of hæm, we hoped to gain some insight into the mechanism of hæm–globin interaction. However, identical results were obtained when the solutions of native globin were replaced by solutions of denatured globin. Most probably, native globin undergoes denaturation when it is spread in the water/xylene interface; it is well known that hæmin combines specifically with denatured globin to form 'globin-hæmochromogen'[4].

The interpretation of the specific drop in the interfacial pressure of globin on addition of hæmin is not quite clear. Earlier[1] we attributed it to the combination of the hæmin molecules with non-polar groups of the globin molecules and concomitant decrease in the affinity of globin to the *p*-xylene layer. Alternately, the drop in the interfacial pressure of globin after addition of hæmin may be due to the formation of globin dimers (or higher polymers) in which the monomers are held together by hæmin bridges so that the total number of protein particles in the interface decreases; this would result in a lower pressure of the interfacial protein film. Both phenomena may be responsible for the enormous drop in the interfacial pressure shown in Fig. 1. Whatever the interpretation may be, the experiments reveal a highly specific reaction between globin and hæmin molecules in the *p*-xylene/water interface.

Cholinesterase Content of the Dog's Lymphocytes and Polynuclears

I have already indicated the presence of cholinesterase in dog's, rabbit's and man's white blood cells[1]. The cholinesterase of the leucocytes is similar to that of the erythrocytes. A technique I have recently described[2] was used for the separation of the various morphological forms of white cells. Since then I have studied the cholinesterase content of dog lymphocytes and polynuclears separately (see Table 1). Determination of the enzyme was based on Michel's method[3].

Table 1. Cholinesterase Content of Dog's Polynuclears and Lymphocytes expressed in ΔpH/hr. The Values are the Average of Eight Experiments

Polynuclears (per mm.)	Polynuclear solution (ml.)	Lymphocytes (per mm.)	Lymphocyte solution (ml.)	Polynuclear cholinesterase	Lymphocyte cholinesterase
8,300	2	4,600	8·1	0·825	0·500

The cholinesterase activity is inhibited by a high concentration (0·06 gm.) of the substrate acetylcholine, whereas it is high at the lower (0·004 gm.) concentration (Table 2). It is therefore suggested that the enzyme may be one of the specific cholinesterases. This type of enzyme is found in both forms studied.

Table 2. Cholinesterase Content of Dog's Polynuclears and Lymphocytes in ΔpH/hr. Note Greater Values at 0·004 gm. Substrate Concentration. The Values are the Average of Three Experiments

Polynuclears (per mm.)	Polynuclear solution (ml.)	Lymphocytes (per mm.)	Lymphocyte solution (ml.)	Polynuclear cholinesterase (0·004)	Polynuclear cholinesterase (0·06)	Lymphocyte cholinesterase (0·004)	Lymphocyte cholinesterase (0·06)
13,800	7	8,800	20·1	1·063	0·246	1·300	0·386

Further work on these lines is being undertaken; details of the results will be published elsewhere.

Effects of Carbon Sources and Base Analogues of Nucleic Acid on the Formation of Bacterial Amylase

A washed suspension of *Bacillus amyloliquefaciens* Fukumoto cells[1], which is a strain of *Bacillus subtilis* that has been used for the industrial production of bacterial α-amylase, secretes a small but distinct amount of amylase when shaken aerobically in the presence of phosphate. Under the same conditions, the addition of a sugar or a salt of an organic acid as the carbon source causes a great increase in the formation of amylase without any addition of nitrogen source[2]. Since the enzyme detected in the autolysate or lysozyme-lysed solution of the bacterial cells is very small, it seems to be certain that the amylase appearing in the cell suspension did not pre-exist in the bacterial cells, but is newly formed and secreted by the cells. In this experiment, however, the amount of enzyme formed differs markedly according to the type of carbon source[3]. As seen in Table 1, there is no clear adaptive relationship between the formation of enzyme and the carbon sources, and also the amount of amylase formed is not in any way parallel to the respiration activity of the cell, which is related to the carbon sources. This characteristic effect of carbon source on enzyme formation is almost always observed, regardless of the type of carbon source on which the cells are grown. Sugars such as glucose and fructose are not only ineffective but may be even somewhat inhibitory, and adding them to other carbon sources which are available for enzyme formation completely nullifies their effect. This diauxic effect[4] appears almost immediately after the addition of these sugars, and remains constant during the course of the experiment, although no metabolic product inhibitory to enzyme formation has yet been detected in the cell suspension system. However, even on a glucose carbon source, good formation of the enzyme occurs to the same extent as from a galactose carbon source, if the glucose concentration is maintained at a very low level (about 0·01–0·02 per cent).

Table 1. Amylase Formation and Respiration of the Cell Suspension on Various Kinds of Carbon Sources

46 mgm. of cells as dry matter, *M*/10 phosphate, 0·5 per cent sugar or *M*/30 organic acid (sodium salt); total vol., 15 ml.; pH 6·8, 10 hr.

Carbon sources	Amylase activity per ml.*	Q_O†	Carbon sources	Amylase activity per ml.*	Q_O†
None	4·0	16	Mannose	5·3	65
Pyruvate	15·0	91	Galactose	21·5	56
Gluconate	15·5	55	Maltose	13·5	81
Xylose	2·7	15	Sucrose	4·0	82
Arabinose	19·5	62	Lactose	24·0	56
Ribose	20·5	67	Soluble starch	17·5	71
Glucose	3·8	92	Mannitol	15·5	—

* The activity of 1 μgm. of crystaline bacterial amylase is taken as one unit (ref. 4).

† Determined after 2 hr. shaking.

Considering these divergent effects of carbon sources on enzyme formation, the following facts seem to be very suggestive. The cells under the experimental conditions indicated in Table 1 secrete

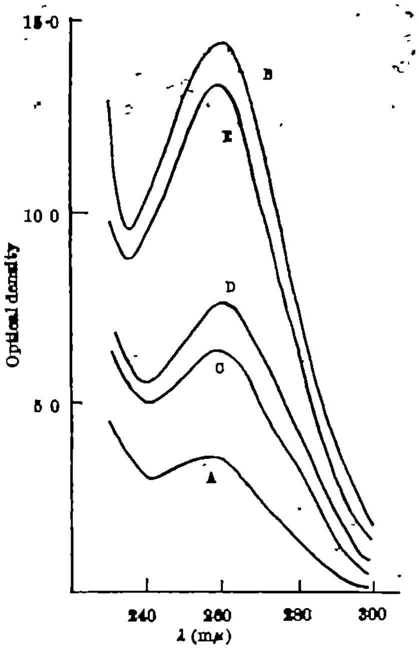

Fig. 1. Ultra-violet absorption spectra of the filtrate of the cell suspension (conditions as in Table 1). *A*, without sugar; *B*, glucose; *C*, galactose; *D*, lactose; *E*, *D* + chloramphenicol (20 μgm per ml.)

several kinds of nucleic acid-bases in a free state, varying in amount with the type of carbon source (Fig. 1). In the presence of glucose (0·5 per cent) the amount is remarkably large, most of it having been identified as uracil. It has been also observed that the formation of amylase in the cell suspension is inhibited by addition of thiouracil or 8-azaguanine, and that the degree of inhibition is dependent on the type of carbon source used in the experiment (Table 2). Severe inhibition is found with carbon sources with which the cells secrete more nucleic acid-bases, and much less inhibition occurs where the cells secrete less nucleic acid-bases. However, with the cell suspension system supplied by a certain nitrogen source, almost complete inhibition occurs upon addition of the base analogue, regardless of the type of carbon source (Fig. 2).

In the cultivation of the bacteria, the amylase activity of the culture filtrate is found to increase most rapidly at the beginning of the stationary phase of cell growth and to reach its maximum at the period immediately before autolysis of the cells. This might lead to the phenomenon reported by Nomura and his co-workers[6], using a certain strain of *Bacillus subtilis*, that bacterial α-amylase formation and cell growth are inversely related. With aerobic shaking of the cell suspension of our bacteria, without addition of any substance, no enzyme is produced; but there is a good formation of spores together with great consumption of cell protein. In the presence of sugar without phosphate, or in the presence of both phosphate and a sugar which is unsuitable for amylase formation, very little enzyme is formed and good spore formation does not occur; but there is secretion of certain kinds of proteins other than amylase, in a considerable amount. On the other hand, under conditions suitable for amylase formation, the amount of nitrogen substances secreted from the cells is relatively small, although the cells show moderate respiration. From the experimental results described above, amylase formation by the cells is greatly influenced by the type and concentration of carbon source added to the cells. This appears to be true, to some extent, in the formation of some other enzymes of the bacterial cells. It is well known that a vigorous protein metabolism always accompanies a vigorous nucleic acid metabolism. The results shown in Table 2 and Fig. 2, however, seem to indicate that the more severe the inhibition of amylase formation by 8-azaguanine, the more vigorous was the original synthesis of nucleic acid taking place in the cells. This leads to the assumption that nucleic acid metabolism of the cells is also greatly influenced by the type of carbon source, especially in the absence of nitrogen source, as seen in Table 2. Thus, it might be concluded that amylase formation by the cells, at least in the absence of nitrogen source, occurs only when extremely moderate metabolism is going on with nucleic acid as well as the carbon source.

Table 2. EFFECT OF 8-AZAGUANINE ON AMYLASE FORMATION

Incorporation of Phosphorus-32 into Salivary-type Chromosomes which exhibit 'Puffs'

A PRELIMINARY study has been made of the rate of incorporation of phosphorus-32 into the chromosomes and associated structures in the salivary gland of a Chironomid, *Metriocnemus hygropetricus*, and since there will be no immediate opportunity to carry the investigation further it seems worth while to present the results, which even at the present stage are not without interest. It has been shown by Prof. H. Bauer (who kindly made available some animals whose progeny were used for this study) that the salivary chromosomes of this species exhibit 'puffs' or Balbiani-rings of various kinds. Larvæ were grown on medium containing phosphorus-32 (as phosphate) for periods of 2–24 hr., and the incorporation was studied in autoradiographs of squashes and sections, which were stained with methyl-green-pyronin and in some cases extracted with ribonuclease or hydrochloric acid.

Both the nucleolus and the puffs stain bright red with pyronin, while the bands in the chromosomes stain with methyl-green; the pyronin staining disappears after ribonuclease digestion. Incorporation of tracer was adequate after feeding the larvæ on labelled medium for 4–8 hr., when the grain counts per unit area over the various components were:

	Cytoplasm	Puffs	Rest of chromosome	Background
4 hr.	14·2 ± 1·4	36·2 ± 2·1	4·9 ± 1·0	2·7 ± 0·1
8 hr.	23·7 ± 2·4	61·4 ± 2·7	6·1 ± 0·8	4·6 ± 0·5

The figures for 4-hr. exposures were taken from 10 cells belonging to 3 larvæ, and those for 8 hr. from 20 cells from 5 larvæ. Nearly all the activity was removed from cells treated with ribonuclease or hydrochloric acid. It is clear that the puffs are very much more active per unit area of squash than the remainder of the chromosomes, which show an incorporation very little above the background. It is not obvious what would be the relative activities of the two types of structure if one used the content of ribonucleic acid as the basis of comparison, since the staining reactions show that this substance is much more highly concentrated in the puffs (and somewhat more in the cytoplasm) than it is in the remainder of the chromosomes.

Demonstration of Early Renal Uptake of Potassium-42 by an Autoradiographic Method for Water-soluble Isotopes of Short Half-life

STUDIES of the distribution of intravenously injected potassium-42 in rats have shown that the kidney takes up this cation from the plasma at considerably higher rates than does any other organ[1,2]. In the first few minutes after the injection, the specific activity in the renal tissues exceeds that of the plasma[3,4]. At 2 min., approximately 15 per cent[1] and 10 per cent[4] of the injected dose were found in rabbit kidneys and about 12 per cent (unpublished observations) in rat kidneys. These fractions are far greater than the expected equilibrium value. Analysis of these findings indicated that all the potassium arriving in the plasma in the kidney is exchanged with potassium from cells. Morel and Gunnebault have recently presented evidence that the renal cortex is the main site of this very rapid exchange[5]. From their experiments it appears that in the rabbit as much as 15 per cent of the total potassium present in the cortex is exchanged per minute. This was corroborated macroscopically by autoradiography in which X-ray films were exposed to 2-mm. thick frozen kidney slices. The resulting autoradiograms indicated that in the 5 min. following an intravenous injection, the intense activity emanated from a region roughly corresponding to the cortex.

The purpose of the present experiments was to obtain information microscopically about the difference in potassium-42 uptake in the various parts of the nephron. Potassium-42 bicarbonate, the chosen carrier, is highly soluble in water. This prevented the use of the traditional histological techniques. Freeze-drying followed by vacuum-embedding was precluded by the short half-life of the isotope (12·4 hr.), no useful exposure of photographic emulsion being possible after three half-lives. The technique described below circumvented these limitations.

After the intravenous injection of 25–100 μc. of potassium-42 into rats, their kidneys were excised at 2 min. and sections prepared for autoradiography or by Gomori's alkaline phosphatase technique[6]. Slices 1–2 mm. thick were promptly transferred into absolute acetone, in which they were fixed for 30 min. This was immediately followed by immersion in polyethylene glycol ('Carbowax 1000') at 44° C. for 1 hr., the shortest period found to allow complete infiltration. The tissues were then blocked in 'Carbowax 1000' and hardened at 3° C. Chemically clean slides were coated with an aqueous solution of 0·0001 per cent chrome alum and 0·005 per cent gelatin, and dried in a dust-free atmosphere. These slides were then flooded with acetone and 10-μ sections floated on to them. With acetone, the surface tension effects which cause disruption of 'Carbowax' sections when flattening is attempted on aqueous solutions did not occur. Acetone also ensured removal of 'Carbowax' without loss of potassium-42.

Groups of three adjacent sections were treated in two ways. The use of Gomori's alkaline phosphatase technique on the first and third section of a group allowed definite identification of proximal convoluted tubules. The middle section was used for autoradio-

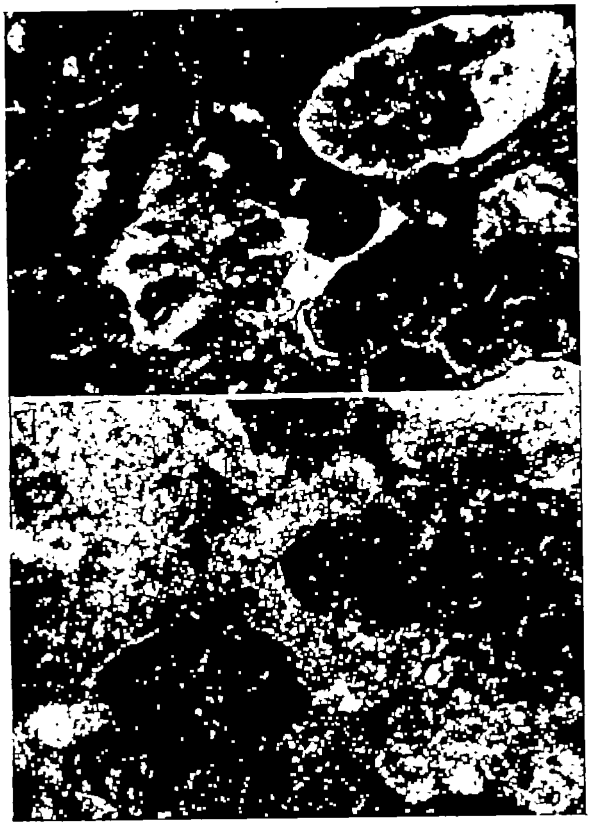

Fig. 2. (a) Alkaline phosphatase preparation of kidney cortex. Proximal convoluted tubules dark. Light microscopy. × 180. (b) Autoradiogram showing distribution of potassium-42 activity in corresponding site of adjacent section. Dark-ground illumination. × 120. Note that the highest radioactivity arises from proximal tubules

graphy. The latter sections were next covered with a 1 per cent solution of 'Perspex' in chloroform. Rapid drying resulted in a thin, uniform layer impermeable to water over the sections. 'Kodak Autoradiographic' stripping film was then wrapped around the slide[6]. After drying in a current of air, the preparations were exposed for three half-lives (approximately 37½ hr.) in darkness over a desiccant (calcium chloride). After mounting in Farrant's medium, the sections were examined by light-, phase- and darkground-microscopy. With this technique it is possible to start exposure four hours after excision of the organ.

Autoradiograms so prepared showed evidence of considerable activity in the cortex but very little in the medulla (Fig. 1). Some regional differences in distribution were found in the cortex, inasmuch as the juxtamedullary part showed more uniform radioactivity than the more peripheral parts. When the various segments of the nephron were compared, the highest activity was found in cells of the proximal convoluted tubules. Comparison of autoradiograms with appropriate areas of adjacent Gomori preparations confirmed this observation (Fig. 2, a, b). In any single section through a tubule, activity was equally present in all cells. This was true of tubules of regions of both high and low activity. Where cytological localization was possible, the potassium-42 was frequently associated with the basal part of the tubular cells. This region contains the mitochondria. The activity was less frequently associated with the region about the brush border and rarely distributed throughout the whole cell.

It seems that this use of acetone does not allow gross leaching of potassium-42 in cells. On the other hand, potassium present in urine and plasma is removed to a large extent and so does not mask activity emanating from intracellular locations.

Tyrosine Peptides as Precursors of Melanin in Mammals

The important role of mammalian tyrosinase in the formation of melanin has been convincingly demonstrated[1]. In all earlier studies, tyrosine has been thought to be the only effective substrate, with the exception of tyrosine ethyl ester which was found by Lerner *et al.*[2] to be oxidized by Harding–Passey melanoma tyrosinase preparations. In a few cases, tyrosine peptides have been investigated as potential substrates, and Bloch[3] found that human skin extracts could not oxidize glycyl-dihydroxyphenylalanine, while Kertész[4] reported that glycyl-L-tyrosine was not oxidized by tyrosinase preparations obtained from human melanomas. Lerner[1] predicted that tyrosine peptides in which tyrosine occupies the *N*-terminal position would be substrates of mammalian tyrosinase, but that tyrosine peptides in which tyrosine occupied the *C*-terminal position would not.

I have been investigating the action of mushroom and mammalian tyrosinase preparations on tyrosine peptides. Early in this work, it became clear that the oxidative activities of the two tyrosinase preparations toward tyrosine peptides were quite different. While L-tyrosyl-glycyl-glycine was oxidized by mushroom tyrosinase, it was not oxidized by mammalian tyrosinase. A number of other tyrosine peptides, including the hormones glucagon, beta-corticotropin, oxytocin and vasopressin, have been studied, using mushroom tyrosinase. Although sufficient amounts of all the hormones were not available, from the peptides and hormones tested, the oxygen uptake was less than five atoms of oxygen per molecule of substrate. However, with mammalian tyrosinase, regardless of the position of the tyrosine residue, an uptake of five atoms of oxygen per molecule of peptide was observed. The nature of the product formed was also quite different. With mammalian tyrosinase an insoluble melanin was formed, whereas with mushroom tyrosinase a soluble polymer formed. Fig. 1 shows the oxygen uptake observed when Harding–Passey melanoma tyrosinase (kindly supplied by Dr. A. B. Lerner) was incubated with (*A*) L-leucyl-L-tyrosine, (*B*) L-tyrosyl-glycine, (*C*) tyrosine, and (*D*) no substrate. In each case, 1 ml. of phosphate buffer (0·1 *M*, *p*H 6·8), 1 ml. of substrate (2·76 micromoles), 0·3 ml. of water, 0·2 ml.

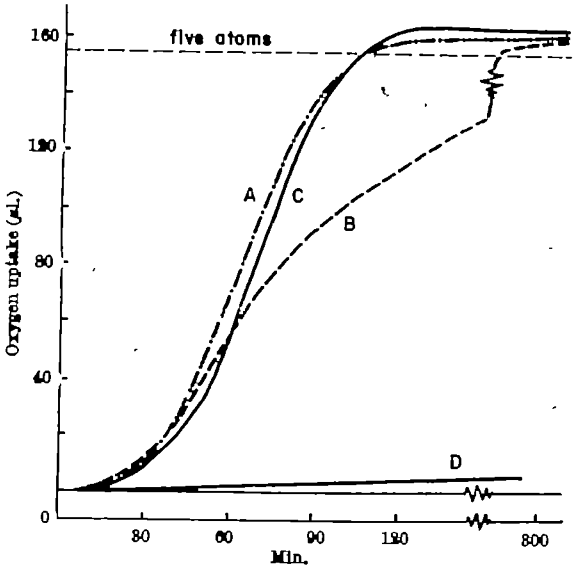

Fig. 1

of 20 per cent potassium hydroxide (centre well), and 0·5 ml. of Harding–Passey melanoma tyrosinase (15 mgm.) were added to each flask and the oxygen uptake measured at 37° C.

The results with mammalian tyrosinase preparations indicated that either the tyrosine peptides were being oxidized intact, or they were being hydrolysed by peptidases to the free amino-acid. To determine which was the case, the reaction mixtures at the end of the manometric experiments were added to 'Dowex-50' (acid form), which would take up any amino-acids present. The resin was then washed, eluted with 5 *N* ammonium hydroxide, and the eluate taken to dryness and chromatographed, using the upper phase of the solvent system *n*-butanol/acetic acid/water (4 : 1 : 5). In each case, free amino-acids were detected corresponding to those which, with tyrosine, formed the peptides. These results demonstrate that there must be a peptidase present which is hydrolysing the tyrosine peptides. Therefore, the reaction sequence with mammalian tyrosinase preparations is as follows :

(1) Tyrosine peptide $\xrightarrow{\text{Peptidase}}$ tyrosine + amino-acid

(2) Tyrosine $\xrightarrow{\text{Tyrosinase}}$ melanin

It must be kept in mind that mammalian tyrosinase is located within melanin granules, and no method has been found which will solubilize the tyrosinase. The peptidases may be within the melanin granules or may be closely associated with them. When the reaction mixtures resulting from the oxidation of the peptides, using mushroom tyrosinase, were chromatographed, no free amino-acids were detected, demonstrating that the peptides were oxidized intact.

Also, evidence has been obtained that esterases are present in the Harding–Passey melanoma tyrosinase preparations, since the total oxidation observed when using mushroom and mammalian tyrosinases are different when tyrosine ethyl ester is used as a substrate. Four atoms of oxygen uptake per molecule of substrate were observed with mushroom tyrosinase, whereas five atoms were observed with mammalian tyrosinase. Experiments are being conducted to detect the ethanol which should be a product of the reaction, if esterases are present.

Thus, it has been shown for the first time that Harding–Passey melanoma tyrosinase preparations can utilize tyrosine peptides as precursors of melanin. Tyrosinase oxidizes the tyrosine which is formed as a result of the action of peptidases on the tyrosine peptide. This work also supports the view that tyrosine is the only monophenolic substrate of mammalian tyrosinase.

Further work is being carried out on the substrate specificity of the peptidase. No detailed studies on peptidases which hydrolyse tyrosine peptides have been reported in the literature. Other sources of mammalian tyrosinase such as the human melanoma and retina have been studied for their ability to use tyrosine peptides as precursors of melanin, and positive evidence has been obtained. A detailed report of this work will be published.

Tooth Eruption Sequence in Fossil and Recent Man

THE sequence of eruption of the permanent teeth has been used as a measure of the biological distance between early and recent man. Schultz[1] gives the order $M_1 I_1 I_2 M_2 (P\ P)\ (C\ M_3)$ for fossil man, as contrasted with $(I_1 M_1) I_2 (P\ C\ P) M_2 M_3$ for recent whites, a distinction in which Osman-Hill[2] concurs. Broom and Robinson[3] have further used the sequence $I_1 M_1 I_2 (C\ P_1) M_2 P_2 M_3$ as a taxonomic criterion for *Paranthropus*, holding that this sequence "agrees closely with that of modern man".

Understandably, the eruption sequences given for the fossils are estimates, with the assumption (usually unstated) that the order of eruption in skeletalized material is equivalent to the order of eruption as seen in the living, and further, that the developmental stages of the teeth provide a reliable indication of the order of eruption.

A study of the dental development of more than 200 white American-born children at the Fels Research Institute, utilizing serial röntgenological and clinical records, shows that the course of dental development is a most variable phenomenon[4]. It was found that the various stages are at best only moderately correlated with each other. Moreover, the eruption of a tooth from the alveolus is by no means comparable to cutting through the gum. Throughout the growth period, the order of development of a given pair of teeth may become reversed and reversed again. In fact, between emergence from the alveolus and the time that the occlusal level is reached, a reversal of sequence may take place. This applies especially to the premolars and to the second molar, which in turn is nearly at the occlusal level before cutting the gum.

It appears that many of the published statements concerning the tooth eruption sequence in fossil man are incorrect, due in part to lack of knowledge of the course of dental development. Weidenreich[5] erroneously assigned the M_2P_2-sequence to *Sinanthropus* on the basis of the location of developing teeth still embedded in the jaw. But the published radiographs of the mandible *B–I* show that the stage of calcification of these two teeth is identical. Judging further from the relationship of the deciduous molar to the underlying second premolar in *B–I*, the eruption sequence in the *Sinanthropus* child would more likely have been P_2M_2. Again, in view of the findings stated in the previous paragraph, there is no conclusive evidence that the Krapina[6], Le Moustier[7], Ehringsdorf[8] and Afalou[9] children would have been M_2P_2. But the assignment of a probable P_2M_2-eruption sequence in the Teshik-Tash child[10] does appear reasonable. Finally, the sequence already given for the South African fossils cannot serve to align them positively with recent man or fossil man.

While it is now doubtful that the M_2P_2-sequence was characteristic of fossil man, it is noteworthy that the M_2P_2 order of eruption through the gum is not uncommon in contemporary peoples. It exists in 16 per cent of Finnish children, as determined at the Finnish Centre for Research in Child Growth and Development, and in the majority of Pima and Apache children examined by Hrdlička[11] half a century ago. Even the M_2C-sequence occasionally appears. Thus the eruption sequence for modern man may well be rewritten as : $(M_1 I_1)\ I_2 (C\ P_1\ P_2\ M_2)\ M_3$, indicating the great deal of variability that does, in fact, occur.

Thus no essential difference has as yet been shown between the eruption sequences of the permanent teeth in fossil and modern man. Therefore, any attempt to utilize the order of eruption as a taxonomic criterion, even assuming that the order was correctly ascertained, is fraught with danger[12,13].

We are greatly indebted to Dr. Arthur B. Lewis, who has maintained the longitudinal collection of dental radiographs at the Fels Research Institute since 1939, and to Mr. Demarest Polacheck for skilful technical assistance.

Partial Albinism in the Syrian Hamster

DURING 1954, and also in 1955, a new mutant white hamster was imported from the United States. The adult mutant possesses pink (pigmentless) eyes and a white pelage but with dark (pigmented) ear pinna. The pigment is dark (melanin) and resides in the skin, the hair on the ears being white. Pigment is also present in the skin of the prepuce (as spots) and in the scrotum of males; and in the perineum region of females. The amount of pigment in the ear appears comparable to that present in the normal golden hamster; but the amount in the genital regions is reduced. The young hamster at twenty-one days of age is devoid of skin melanism, with flesh-pink ears. By twenty-six days of age (range 24–28 days) the ears are distinctly tinged with pale grey. By the thirty-first day the ear colour is grey; thereafter the ear darkens more slowly, eventually becoming black. Some 2–3 months may elapse before pigment is manifested in the genitals. These observations strongly suggest that the phenotype is that of a thermo-sensitive acromelanic albino (such as the Himalayan rabbit or Siamese cat). The symbol c^d is proposed for the mutant allele.

Preliminary experiments determined that the allele is inherited as a recessive. Reciprocal crosses of normal × albino gave a normal F_1 and an F_2 segregation of sixty-nine normal and twenty-five albino ($\chi_1^2 = 0.128$; $P > 0.70$). Recently, the results of two extensive series of matings have been completed. The first of these has yielded an F_2 segregation of 1,019 normal and 356 albino ($\chi_1^2 = 0.582$; $P > 0.30$). The second series produced an F_2 generation of 476 normal and 143 albino ($\chi_1^2 = 1.190$; $P > 0.10$). Heterogeneity between the three groups is negligible ($\chi_2^2 = 1.890$; $P > 0.10$). No association was found to exist between partial albinism and sex ($\chi_1^2 = 1.397$; $P > 0.20$).

The second series of matings were designed to test for linkage between c^d and *ru* (the latter a ruby-eye mutation reported earlier[1]). The F_2 generation from $c^dRu/Cru \times c^dRu/Cru$ gave the following distribution.

CRu	Cru	c^dRu	c^dru
394	82	123	20

There is a deficiency of *ruru* animals; but this phenotype is known to be sub-viable compared with the normal hamster. However, the four classes analysed as a 2 × 2 table do not disclose an association between the simultaneous segregation of the two alleles ($\chi_1^2 = 0.839$; $P > 0.30$). It may be noted that the estimate of viability of *ruru* zygotes for the present data (0.5919 ± 0.0702) does not differ significantly from that previously reported (0.4773 ± 0.0869).

An interesting item from this segregation is the appearance of a 'synthetic albino'. The phenotype c^dc^druru possesses pink eyes and white fur but also flesh-coloured ears and genitals. This is the result of the mutual action of the two genes. The ruby-eye hamster has peach-grey ears and little or no melanin about the perineum. The ear colour of the synthetic albino varies from clear flesh-pink to peach-grey but not apparently attaining the same degree of peach-grey found in the ruby-eye. The reason for this is not obvious; but it is implicit that the thermal threshold of pigment production in c^dc^druru animals may be higher than that in C-*ruru*.

I wish to thank Mr. G. T. C. Gore for kindly recording the data for the first series of matings.

Experimental Studies of Mimicry in some North American Butterflies

Experiments have been conducted to test the effectiveness of presumed mimicry in two groups of North American butterflies: (1) *Danaus plexippus* Linn. (model) and *Limenitis archippus archippus* Cram. (mimic), the monarch and viceroy respectively; (2) *Battus philenor* Linn. (model) and *Papilio troilus* Linn., *P. polyxenes* Stoll, and *P. glaucus* Linn. (black female) (mimics).

Eight caged Florida scrub jays (*Cyanocitta coerulescens coerulescens* Bosc) were used as predators in feeding experiments in which they were given presumed models and mimics, as well as non-mimetic butterflies. For the purpose of this communication, non-mimetic butterflies are those butterflies which are not involved in mimicry either as mimics or models. These studies were carried out at the Archbold Biological Station in southern Florida in the spring of 1956. The same individual birds, with the exception of one, were used throughout both groups of experiments, which were carried out in the order listed above.

After preliminary tests with various orders of insects to accustom the eight birds to laboratory conditions, four were randomly selected as experimental birds; the remaining four were control birds. Throughout the experiments each butterfly, if alive, was immobilized by pinching the thorax before it was given to a bird. Each butterfly was placed in a lateral position on the floor of the cage, and each bird was allowed a total of 2 min. to react to each butterfly given. The treatment of each butterfly by each bird was recorded according to four categories: (1) not touched; (2) pecked, but not injured; (3) killed or injured, but not eaten; (4) eaten. A total of 2,508 butterflies was given to the birds in the course of these experiments. The following procedure was used in the experiments with both mimicry complexes.

Experimental birds: (*a*) Each experimental bird was given approximately fifty trials with models; and with non-mimetic butterflies which were shown in the preliminary tests to be palatable to all the birds. Each trial consisted of the presentation of two butterflies: one model and one non-mimetic butterfly. The order of presentation of these in any given pair was determined with a table of random numbers.

(*b*) After the fifty initial trials with models and non-mimetic butterflies, the experimental birds were given mimics in place of models.

Control birds: The control birds were given mimics and non-mimetic butterflies; the same species of non-mimetic butterflies and the same method of presentation described for the experimental birds were used. The control birds were never given models.

The results showed that the non-mimetic butterflies were eaten in every case by all eight birds throughout all the experiments. It was found that the experimental birds, after they had pecked models in the first few trials, would 'not touch' models on sight alone in 205 out of 339 trials (60 per cent) for *D. plexippus*, and in 161 out of 209 trials (77 per cent) for *B. philenor*. The experimental birds ate none out of 339 (0 per cent) *D. plexippus* given to them, and only 2 out of 209 (1 per cent) *B. philenor*. When mimics instead of their models were offered in later trials with these experimental birds, the 'not touched' treatment of mimics was as follows: 42 out of 60 trials (70 per cent) for *L. a. archippus*; 27 out of 41 trials (66 per cent) for *P. troilus*; 12 out of 13 trials (92 per cent) for *P. polyxenes*; and 6 out of 12 trials (50 per cent) for *P. glaucus* (black female). The experimental birds ate none out of 60 (0 per cent) *L. a. archippus* presented; 9 out of 41 (22 per cent) *P. troilus*; 1 out of 13 (8 per cent) *P. polyxenes*; and 3 out of 12 (25 per cent) *P. glaucus* (black female).

In contrast to the experimental birds, the control birds, having had no laboratory experience with models, did 'not touch' the mimics in only 10 out of 100 trials (10 per cent) for *L. a. archippus*; none out of 392 trials (0 per cent) for *P. troilus*; none out of 40 trials (0 per cent) for *P. polyxenes*; and none out of 12 trials (0 per cent) for *P. glaucus* (black female). Moreover, the control birds ate the mimics in 60 out of 100 trials (60 per cent) for *L. a. archippus*; 392 out of 392 trials (100 per cent) for *P. troilus*; 39 out of 40 trials (98 per cent) for *P. polyxenes*; and 12 out of 12 trials (100 per cent) for *P. glaucus* (black female).

The results given above are lumped for all the experimental birds, and for all the control birds. It should be remembered that, in experiments with caged predators, the predator is actually afforded a closer and longer scrutiny of a model or mimic than would usually be possible under natural conditions, where an attacking bird might get only a glimpse of a flying butterfly.

The treatment ('not touched' *vs.* 'pecked–killed–eaten', and 'not touched–pecked–killed' *vs.* 'eaten') of the mimics (*L. a. archippus, P. torilus* and *P. polyxenes*) by the experimental and control birds was analysed with the chi-squared test on the hypothesis, in each case, that both sets of birds treated the mimics the same; the calculated values for P were less than 0·001. The significant difference in treatment is attributed to the fact that the experimental birds had about fifty initial trials with each model before experiencing the mimic; the colour pattern of the model, in each case, was associated with the learned unpalatability of that butterfly. Then when the mimics were presented, the experimental birds in general were unable to discriminate the colour pattern of the mimic from that of the model. Under the conditions of the experiment, the effectiveness of mimicry in the case of *L. a. archippus*, and of *P. troilus* and *P. polyxenes* has been demonstrated.

Full results and an extended discussion of these experiments and others will appear elsewhere at a later date. This work was aided by a Fanny Bullock Workman Scholarship from Wellesley College and a National Science Foundation terminal predoctoral fellowship.

Status of *Moerisia lyonsi* Boulenger and Related Hydroids

Last year, when considering evolutionary trends in capitate hydroids and medusæ[1], I was astonished by the remarkable similarity between some of these forms (*Euphysa* hydroids and *Sarsia* medusæ) and the hydroid and medusa of *Moerisia lyonsi* Boulenger[2]. The latter and related species of the family Moerisiidae have for some time been placed in the Limnomedusae[3], an order which includes such diverse forms as *Proboscidactyla* (*Lar*, the posturing polyp of Gosse) and *Craspedacusta* (the freshwater medusa).

Consideration of the important features of the Moerisiidae common to other Limnomedusae revealed these were: a quadrate stomach, tentacles which were either hollow or had an endodermal core consisting of more than a single row of cells, and the semblance of an endodermal root in the tentacles of the medusa[4]. These characters in themselves are not enough to warrant the separation of the Moerisiidae from the Capitata (with which their morphological characteristics strongly suggested they belonged) and I sought for additional links with other Limnomedusae. It was thought that the cnidome (the nematocyst armature) might reveal more positive evidence in favour of Limnomedusan affinities, but the three best-known species[5] have a tricnidome consisting of stenoteles, desmonemes and atrichous haplonemes[6]. This grouping of nematocyst types is essentially a capitate one, which is, moreover, distinct from the nematocyst pattern in the other two Limnomedusan families. The quadrate stomach of the medusa cannot be regarded as more than a variant of the basic pattern seen in the Capitata as its gonad is continuous and unbroken. The other two characteristics mentioned could arise independently in almost any family of medusae, and are probably far less significant than evidence based on nematocysts. For these reasons, which will be more fully discussed elsewhere, the family Moerisiidae is placed in the sub-order Capitata of the order Anthomedusae.

Stimulation of Sclerotium Germination in *Sclerotium cepivorum* Berk.

Earlier work by Scott[1] demonstrated the inability of *S. cepivorum*, the cause of white rot disease of onions, to grow or survive, in soil, in the form of mycelium, and focused attention on the biology of its sclerotia, which are produced in large numbers on the base of infected plants.

Sclerotia from cultures grown for six weeks on sand – maize-meal slopes at 20° C. were shown to persist in undisturbed field soil for at least three years in the absence of the host plant. Using as inoculum sclerotia which had been buried for less than two months in soil, no infection occurred but there was heavy infection of onion seedlings inoculated with sclerotia which had been buried for longer periods. Accordingly, sclerotia used in germination experiments were taken from soil after six months burial.

Table 1. Percentage Germination of Sclerotia in Soil and Sand with or without Onions

Medium	Water holding capacity (per cent)	With (+) Without (–) onions	Germination (per cent)
Soil	60	+	83·3
,,	60	–	0·0
,,	40	+	64·6
,,	40	–	0·0
Sand	60	+	62·5
,,	60	–	0·0
,,	40	+	45·8
,,	40	–	0·0

Onion seedlings were inoculated, before being transplanted singly into tubes of soil, at 40 and 60 per cent water-holding capacity, by placing a sclerotium between the roots at the base of the bulb. On lifting the infected plants it was possible to see that the sclerotia had germinated characteristically by the formation of a plug of hyphæ which emerged after the rupture of the rind. In experiments of this kind levels of germination of sclerotia averaged 60–92 per cent, whereas in the control tubes without onions, germination was usually 0 per cent, and, rarely, up to 15 per cent.

In further experiments, moist nylon strips measuring 11 cm. × 2·5 cm. were placed inside 4 in. × 1¼ in. glass specimen tubes, in contact with the glass, near the top. Sclerotia were placed in a ring between glass and nylon at the rate of twelve sclerotia per tube. In half the tubes twenty-four white Lisbon onion seeds were similarly placed 1 cm. above the sclerotia. Soil or sand was then added to the tubes and kept at a constant water-holding capacity, at laboratory temperature. After eight weeks the levels of sclerotium germination were recorded (Table 1). Each value is an average of four replicates.

That the stimulatory effect of onions was not dependent upon contact between sclerotium and root was indicated by the fact that many of the germinating sclerotia were up to 1 cm. distant from onion roots.

Using onion seedlings which were germinated on moist filter paper in Petri dishes, 100 per cent germination of sclerotia occurred when they were placed in contact with any part of roots which had previously been damaged by needle pricking. On undamaged roots there was 97·5, 47·5 and 57·5 per cent germination of sclerotia placed, respectively, on root tips halfway between tip and base, and on base of bulb. Sclerotia placed on moist filter paper in Petri dishes did not germinate.

The addition of water extracts of roots of onion, shallot, and leek also had a marked stimulatory effect on the germination of sclerotia in soil. Quoting the results of one particular experiment, average germination figures of 86·7, 93·3 and 73·3 per cent were obtained, respectively, with extracts of onion, shallot and leek. No germination occurred, however, using extracts of roots of cabbage, brussels sprout and barley, or when distilled water alone was added.

These investigations are proceeding with the object of isolating and identifying the stimulatory substance.

FORTHCOMING EVENTS

Wednesday, September 4

Institute of Petroleum (at 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. A. Kranendonk (N.V. De Bataafsche Petroleum Mij.): "Some Developments in Marine Drilling Foundations".

Wednesday, September 4—Wednesday, September 11

British Association for the Advancement of Science (at Dublin).—Annual Meeting.

Wednesday, September 4

At 7.30 p.m.—Prof. P. M. S. Blackett, F.R.S.: "Technology and World Advancement" (Presidential Address).

Thursday, September 5

At 10 a.m.—Prof. J. Z. Young, F.R.S.: "The Evolution of Organization in the Nervous System" (Presidential Address, Section D).

At 10 a.m.—Prof. Sir Lindor Brown, F.R.S.. "Chemical Transmission at Nerve Endings" (Presidential Address, Section I).

At 10 a.m.—Prof. J. Doyle: "Aspects and Problems of Conifer Embryology" (Presidential Address, Section K).

At 10 a.m.—Sir James Turner: "The Role of Agriculture in the British Economy" (Presidential Address, Section M).

At 11.15 a.m.—Mr. T. McEvoy: "Forestry in Ireland" (Chairman's Address, Section K*).

At 11.30 a.m.—Dr. J. W. Cook, F.R.S.: "Chemical Approaches to the Investigation of Lung Cancer" (Presidential Address, Section B).

At 11.30 a.m.—Prof. J. E. Meade; "The Balance-of-Payments Problems of European Free Trade" (Presidential Address, Section F).

At 11.30 a.m.—Dr. H. G. Maule: "The Worker and his Work" (Presidential Address, Section J).

At 2.15 p.m.—Prof. C. F. C. Hawkes: "Archaeology as Science: Purposes and Pitfalls" (Presidential Address, Section H).

At 2.15 p.m.—Prof. D. A. Webb: "The Vasculum and the Microtome—the Relationship between Natural History and Laboratory Biology" (Presidential Address, Section X).

At 8 p.m.—Mr. G. F. Mitchell: "Ireland in Antiquity: the Chronological Background" (Evening Discourse).

Friday, September 6

At 10 a.m.—Prof. T. G. Cowling, F.R.S.: "Stellar Energy and Stellar Evolution" (Presidential Address, Section A).

At 10 a.m.—Sir David Anderson: "Education and Training for the Engineering Industry" (Presidential Address, Section G).

At 11.30 a.m.—Prof. David L. Linton: "The Everlasting Hills" (Presidential Address, Section E).

At 11.30 a.m.—Mr. L. R. Missen: "The Education of the Countryman" (Presidential Address, Section L).

At 8 p.m.—Dr. H. J. Bhabha, F.R.S.: "On the Economics of Atomic Power Development in India and the Indian Atomic Energy Programme" (Evening Discourse).

Sunday, September 8

At 11.15 a.m. (in St. Patrick's Cathedral)—Religious Service. Preacher: The Lord Archbishop of Dublin.

Monday, September 9

At 10 a.m.—Dr. G. H. Mitchell, F.R.S.: "Ordovician Volcanoes" (Presidential Address, Section C).

At 8 p.m.—Sir Sydney Caine: "Education for Development".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant, Grade B, in the Mathematics Department, to teach Mathematics (Pure and Applied) to the level of the higher national certificate and B.Sc. General Degree Part I—The Principal, Derby and District College of Technology, Normanton Road, Derby (September 7).

Head (with a good honours degree in physics, together with a research degree, the Fellowship or Associateship of the Institute of Physics and teaching experience, preferably in a technical college or university) of the Physics Department—The Principal, Wigan and District Mining and Technical College, Wigan (September 7).

Senior Lecturer (with a degree in physics, and industrial, research and teaching experience, and preferably a special interest in some branch of applied physics) in Physics—The Clerk to the Governing Body, Brunel College of Technology, Woodlands Avenue, Acton, London, W.3 (September 7).

Miles Ames Fellow (with a Ph.D. degree or equivalent in chemistry, biochemistry or an allied subject) in Endocrinology, to carry out original work on steroid hormones or on any other aspect of endocrinology in which he or she is particularly competent—The Secretary, King's College Hospital Medical School, Denmark Hill, London, S.E.5 (September 14).

United Steel Companies' Research Fellow (with some research experience) in the Department of Metallurgy, to work on the purification of iron by zone melting and to make a systematic study of the properties of high purity iron and its alloys—The Registrar, The University, Sheffield (September 16).

Hydrologist (with a university honours degree or equivalent with chemistry as a major subject, and some physics and mathematics and postgraduate research experience, preferably in a marine hydrological laboratory) in the Division of Fisheries and Oceanography, Commonwealth Scientific and Industrial Research Organization, Sydney, New South Wales, to take part in a research programme o the chemistry of Australian coastal waters—Chief Scientific Liaiso Officer, Australian Scientific Liaison Office, Africa House, Kingsway London, W.C.2, quoting Appointment No. 330/128 (September 21).

Director (with suitable qualifications and considerable experienc in museum work) of City Museums—The Town Clerk, Civic Hal Leeds 1 (September 30).

Gum Research Officer (with a thorough knowledge of forestry an appropriate university degree, and experience in tropical forestr and research work and modern sylvicultural practices) in the Forestr Department of the Ministry of Agriculture, Sudan—Sudan Embassy Personnel Section, Cleveland Row, St. James's, London, S.W. quoting Ref. "Gum Research Officer 4/445" (September 30).

Senior Lecturer in Theoretical Aerodynamics—The Recorder The College of Aeronautics, Cranfield, Bletchley, Bucks (September 30).

Senior Lecturer (with a Doctorate of Philosophy or Scienc conferred for research in some branch of physics, and preferably som lecturing experience) in Physics, at the University of Queensland Australia—The Secretary, Association of Universities of the Britis Commonwealth, 36 Gordon Square, London, W.C.1 (Australi September 30).

Chair of Applied Mathematics—The Registrar, Universit College of Wales, Aberystwyth (October 7).

Research Assistant (with a good honours degree in physics an some postgraduate experience in high vacuum work) in the field o Vacuum Spectroscopy—Prof. R. W. Ditchburn, The University Reading (October 15).

Reader in Geophysics at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Common wealth, 36 Gordon Square, London, W.C.1 (Australia, November 15

Biochemist, Basic grade (with a first- or second-class honou degree in chemistry or biochemistry)—The Medical Superintenden Royal Infirmary, Glasgow, C.4.

Geophysicist (preferably single, with an honours degree in geolog or physics and a good knowledge of magnetometer survey) with th Falkland Islands Dependencies Survey, for service in the Antarcti for eighteen months under conditions which are a test of character an resource—The Crown Agents, 4 Millbank, London, S.W.1, quotin M.3B/44253/NF.

Instructor or Assistant Professor (with the Ph.D. degree o equivalent) in Entomology—Prof. I. McT. Cowan, Department o Zoology, University of British Columbia, Vancouver, B.C., Canada.

Laboratory Steward in the Chemistry and Biology Department—The Registrar, College of Technology, Park Road, Portsmouth.

Lecturer, Assistant Professor, or Professor (with a Ph.D degree and experience in teaching and research) in Bacteriology at the College of Arts and Science, Baghdad, Iraq—The Cultura Attaché, Iraqi Embassy, 22 Queen's Gate, London, S.W.7.

Lecturer, Grade B (graduate of a British university, and prefer ably an interest in statistics or the industrial application of mathe matics) in Mathematics—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11.

Scientific Officers (with a first- or second-class honours degre in appropriate scientific subjects, or equivalent qualifications, an preferably some knowledge of electronics) at the Atomic Weapon Research Establishment, Foulness, Essex, for the developmen and application of instrumentation for research on explosives an properties of materials under conditions of high pressures and tem peratures, with opportunities for original design work in the solutio of unusual problems—The Senior Recruitment Officer, Atomi Weapons Research Establishment, Aldermaston, Berks, quoting Ref 1563/34.

Senior and Junior Research Fellows (with a first- or second class honours degree in an appropriate subject, and able to show evidence of a very high standard of ability in research) at Governmen Scientific Establishments, for research into subjects of importance t H.M. Government—The Civil Service Commission, Scientific Branch 30 Old Burlington Street, London, W.1, quoting S.4695/57.

Senior Technician (preferably with higher national certificate o equivalent qualifications) for electronics work in connexion with 30 MeV. synchrotron and other projects—The Secretary, Institute o Cancer Research, Royal Cancer Hospital, Fulham Road, London S.W.3.

Systematic Botanist and Ecologist (with an honours degree in botany and at least two years research experience preferably in ecology; or an honours degree or equivalent in agricultural science plus two years completed postgraduate training in botany, preferably with an ecological bias) in Sierra Leone, to carry out ecological studies appertaining to agricultural and forestry field problems (including the maintenance and enlargement of a herbarium)—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD/63/15/012.

Zoo Superintendent (preferably with wide zoological and administrative experience)—The Secretary, Bellevue Zoological Gardens, Manchester 12.

LIGHT, COLOUR AND VISION

by

Yves Le Grand

(Professor at the Muséum National d'Histoire Naturelle, Paris)

Translated from the French by

R. W. G. Hunt Ph.D., D.I.C., A.R.C.S., F.R.P.S.
J. W. T. Walsh O.B.E., M.A., D Sc.
F. R. W. Hunt O.B.E., M A., F.Inst.P.

Size 8¾ in. × 5½ in. *528 pages* *125 illustrations* *63s. net*

This is a translation of the second volume of a comprehensive three-volume treatise on vision. In it the eye is considered as a receptor of radiant energy. The point of view expressed is essentially that of the physicist, though the physiological aspect, which alone can explain the functioning of the retina and of the nervous relays, is not ignored. The aim, however, is to give as much practical information and numerical data as possible concerning the response of the eye to radiation.

PRECISION INSTRUMENTS

Photo-electric Polarimeter

for visible and ultra-violet regions

A fully automatic instrument for use in the region 2,300 A to 6,500 A
is being developed
with an accuracy of at least .005 angular degrees.

If desired, the automatic rebalance servo may be disconnected to give manual control.

Direct reading scale presentation avoiding the use of eyepieces will be a feature of this instrument which will go into production early in 1958.

PROGRESS IN UNDER-DEVELOPED COUNTRIES

THE committee appointed by the Council of the British Association to consider, under the chairmanship of Sir Ben Lockspeiser, the functions of the British Association in the world to-day, expressed the view that one of its purposes is to provide for non-specialists—whether they be scientists outside their own field or interested laymen—an annual stocktaking in intelligible language which will review the progress of science and help to make clear its significance and possible consequences. It is imperative, the committee held, that scientists and laymen should be seen to accept the need to anticipate and debate the social and political consequences of science. Moreover, such discussions should also serve to make it clear that modes of thought, other than the scientific one, must contribute to the solutions of problems created by scientific discovery.

Accepting this advice as wise, Prof. P. M. S. Blackett has not been deterred from following it in his presidential address by the inherent risk of becoming controversial (see p. 473 of this issue of *Nature*). That risk he regards as inevitable, because in science and technology lies the key to wealth, the creation and distribution of which are the warp and woof of the many-patterned texture of politics. Nor is this to be avoided by the rapid development of the social sciences for which Lord Adrian pleaded at Oxford in 1954. The facts discovered by social scientists, including economists, and the theories they elaborate, cannot by themselves, he points out, define the objectives of social policy. These goals must ultimately be determined by the judgment of value made by individuals. The social scientist may assist us to think rationally about alternative uses for our material wealth and may assist us to attain whatever end we choose. He cannot choose for us how much of the wealth resulting from technological advance should be devoted to the production of more material goods, and how much to more personal leisure and to gracious living; how much to providing greater consumption now, and how much should be set aside for the future; how much to greater opportunity for youth and how much to greater security or luxury for old age; or how and to what extent should different kinds of ability and enterprise be rewarded.

It is, of course, the different values attached to various objectives by particular groups or individuals that are responsible for most political controversy and tension to-day, both within a nation or on the international plane. The social scientist can sometimes, as Prof. Blackett observes, show us how best to attain our chosen end, and he may also help us to do so in such a way as to minimize friction and tension. It is no less true that the social scientist can warn us when the policy we seek to pursue in furtherance of our purpose is incompatible with either our resources or with the systematic observations which form the body of his science.

In this address, however, Prof. Blackett comments on the very uneven distribution of material wealth in the contemporary world and the attention that economists are now giving to the complex historical causes which lead a country to transform itself from a static pre-industrial State to a growing industrial one; and he goes on to discuss the question of how best the Western world can help to reduce a gap in wealth between the West and Asia which is steadily widening. The potentialities of nuclear power for the under-developed countries have not always been very realistically discussed. As Prof. Blackett remarks, most new scientific and technical discoveries or developments tend to widen the gap still more, just because the rich countries have the capital to make full use of them, whereas the poor countries have not. Under present conditions, the advent of nuclear power must tend to widen the absolute gap still further, because of the high capital cost of nuclear power stations, although it is of course in this context that the smaller nuclear power units of 30 MW. or less capacity may be important.

Be that as it may, Prof. Blackett is right to remark that scientific and technical invention is no fairy wand to wave over a poor country to transform it into a rich one. Apart altogether from the question of an adequate supply of technicians, technologists and able administrators, and of finding the necessary capital internally and externally, there are moral factors and judgments of value involved. Prof. Blackett points out that the saving and investment required for the initial industrial development in Britain were provided by the prosperous classes, who did not spend their surplus wealth on ostentatious living but invested it in productive industry. It might also be observed in this context of assisting the under-developed countries that the political conditions in Britain at the time encouraged such investment because of the confidence they inspired.

In glancing at the present position of the under-developed areas, and more particularly at what is being done in India to deal with the situation, Prof. Blackett notes that the limit of their advance is set mainly by the available capital for productive investment, and particularly of foreign exchange to buy production goods from other countries. Failing massive external aid, the advance is limited to what a democratic parliamentary government of a very poor country can raise internally by taxation and loans. Prof. Blackett admits the importance of the population problem and, though he notes that the governments of both India and China have already taken steps to reduce the increase in population, he recognizes also that success here can only be achieved by education, which itself is dependent on increasing wealth and in turn on industrialization as part of a general social advance, with more efficient agriculture and thus a greater food supply.

Prof. Blackett's glance at the historic origin of the remarkable differences to-day between the economic and social conditions of the West and the East does not offer much guidance as to how to reduce the gap, though he notes the importance of the weakening of the opposition of organized religion to the free play of scientific experiment and speculation for the scientific revolution of the seventeenth and eighteenth centuries and the industrial revolution which followed in Britain. How important this factor can be even to-day is seen in the way in which political prejudice in Arabia impedes, and may even frustrate, international efforts on locust control. Possibly Prof. Blackett is inclined to under-rate the importance of this political climate in his confidence in the possibility of social advance in the ex-Colonial Asian countries and his reliance on massive financial help. He suggests that the need for technical assistance has been over-estimated, and that for simple financial help under-estimated. Whether, in fact, the expert aid by Western technical personnel needed by an under-developed country is more efficiently and cheaply provided by direct financial advance, leaving the country itself to engage the personnel it needs, depends a good deal on the vision and administrative character of the government of that country.

Prof. Blackett's lack of faith in technical assistance finds little support either in Dr. Gunnar Myrdal's study of the problems and prospects of an international economy published in 1956, or in the latest report of the Consultative Committee for the Colombo Plan (London: H.M.S.O., 1957), or of the Technical Assistance Board of the United Nations Economic and Social Council (United Nations, New York, 1957), although in general his argument as to the vital importance of massive assistance is fully substantiated. The Colombo Plan report stresses the need for flexibility in development and the continuing opportunities for adding to existing skills in these backward areas, for co-operation and further sources of external capital both from foreign private investment and public and private loans, while pointing, like Prof. Blackett, to the difficult decisions which will be required in assessing the extent to which the fruits of development can and should be devoted to consumption rather than investment. Specifically, it comments that the increasing effort in the field of technical assistance and the more varied ways in which this assistance is being given are removing a main impediment to economic development in the Colombo Plan area, and that technical assistance is more than a matter of helping to overcome a lack of technical personnel, and that its value cannot be assessed simply in statistical terms.

Equally significant is the comment in the report for 1956 of the Technical Assistance Board that the ability of a country to develop its resources and to take full advantage of technical assistance in any of its specialized fields is closely related to the stage of development of its basic institutional framework and of its administrative organization. Moreover, soundly based requests for technical assistance greatly exceed in volume the resources the Board at present has to meet them and even if, as is hoped, these resources increase, the Board contemplates some concentration in future development on the neediest countries and territories. Nor does the report give any impression that the available resources are not now wisely and efficiently administered. Much of the earlier criticism appears to have been heeded and overlapping eliminated so far as possible, although it would still appear possible for more to be done by the Board and by other agencies to establish an international service on which the under-developed countries could call for experts.

There are, of course, real difficulties in that direction; but such a step would go far to meet the fundamental point which Dr. Myrdal makes, that assistance to under-developed countries, whether in the form of capital or of experts, should be given so far as possible through international agencies with responsibility for making policy. As to the value of technical assistance itself, Dr. Myrdal has not the least doubt. Even in the industrial field he considers it has a part to play and one which can only be effectively fulfilled on an international constitutional basis, as within the United Nations. In practice, it would be both psychologically and politically impossible to withdraw; and Dr. Myrdal agrees with Prof. Blackett that technical assistance is sometimes misunderstood—it is not, for example, a cheap way of assisting the under-developed countries—and points out that technical assistance is no substitute for credits and capital aid. In the main, the under-developed countries will have to pay for the industrial techniques and knowledge they require; but technical assistance tends to mobilize the latent needs for capital, and the more it is made available and the more effectively it is applied, the larger, the better prepared and the more articulate will be the demands for capital.

Where Dr. Myrdal and Prof. Blackett agree even more emphatically is that an important contribution to narrowing the huge gap in material living standards between the industrial and pre-industrial countries outside the Soviet orbit could be made at relatively small cost to the rich industrial countries. Prof. Blackett puts the figure at an additional £1,000 million a year as a free gift or as long-term loans; Britain's contribution of £150 million a year would only postpone by less than a year the expected rise of 50 per cent in British living standards over the next quarter of a century. Prof. Blackett is firmly of opinion that the West should make this great experiment of sacrificing some of its immediate prosperity to give massive aid to the under-developed countries; and if the major nations of the West cannot agree quickly to provide the required £1,000 million, he believes that Britain should make her contribution of £150 million a year available to her former Colonies in addition to what she is already doing.

Prof. Blackett sets this as a special challenge to scientists and technologists, since it is their genius and skill which alone can bring the material basis of happiness within the reach of all, though, as already suggested, he is inclined to pass over the more specific contribution which they could make in the field of technical assistance. There is much in his address to suggest that he is familiar with Dr. Myrdal's book, though he does not refer to the help which greater internationalism in university life and the gradual building up of a large number of research and training institutions in the under-developed regions could give—tasks in which the scientists and technologists can help as such, not simply as citizens. There is, moreover, a certain danger in the suggestion that Britain should act alone. Dr. Myrdal's argument for aid through international institutions rests in part on the desirability of a fairer distribution of the burden among the richer countries, and even if such unilateral aid did not encourage the political element and pressure politics, it could scarcely achieve the desired stability. Nevertheless, Prof. Blackett has challenged the British Association to some clear thinking and, however much his plan may require careful scrutiny and re-examination on points of detail, he will have earned the thanks both of the Association itself and of a much wider circle in the Commonwealth whose interests to-day the Association has re-affirmed its desire to serve, if action can be taken to prompt the imaginative Colonial experiments he suggests.

HARVEIUS REDIVIVUS

Movement of the Heart and Blood in Animals

By William Harvey. Translated from the original Latin by Prof. Kenneth J. Franklin. (English and Latin text.) Pp. xii+209. (Oxford: Blackwell Scientific Publications; Springfield, Ill.: Charles C. Thomas, 1957. Published for the Royal College of Physicians of London.) 17*s.* 6*d.*

THE plan of this work covers the following material: dedications to King Charles I and to other physicians; introduction; new English translations of the foregoing and of the seventeen chapters of the 1766 edition of "De Motu Cordis"; reprint of the Latin text of the same edition after revision of the punctuation and correction of typographical and editor's emendations.

In this English translation of Harvey's work on the circulation, Prof. K. J. Franklin had three predecessors, and his method was to make his own translation first, and then to compare it with those of his rivals. This is an admirable and courageous method, since it cannot be said that the result is only a modification or improvement on what has been done before. Robert Willis's well-known translation was published in 1847, and is indeed the "standard rendering to date", according to Franklin. Its literary style is grandiose and in places distinguished by a colourful imagination, but its scholarship is at times open to question and may even be difficult to follow. Prof. Franklin's work is therefore not only a new translation but is also undoubtedly free from the faults and shortcomings of previous authorities. In only a very few cases would one wish to modify his version. In the preface, when discussing the existence of pores in the ventricular septum, which would permit blood passing direct from the right ventricle into the left, Harvey says: "Sed me hercule porositates nullae sunt, neque demonstrari possunt", which is translated: "But, damme, there are no pores and it is not possible to demonstrate them". It may be doubted whether Harvey ever used this expletive, and the translation "by Hercules" given in contemporary Latin dictionaries is a more probable alternative and does in fact occur in Harvey's writings. Another passage, at the end of Chapter 16, is more important as giving the enemy occasion to blaspheme. Franklin describes certain veins as being 'distributed' to the stomach and intestine. The Latin verb used is not *distribuo* but *dissemino*, which is rare in classical Latin and should be translated not as 'distributed to' but as 'spread over' the gut. The rest of the paragraph makes it clear that the blood in these vessels is returning *to* the heart.

It is often stated that Harvey owes the discovery of the circulation to the work of his teacher Fabricius on the valves of the veins. This belief is not borne out by an examination of the plan of the 1628 volume. Fabricius himself did not discover the valves, which were known to Canano some sixty years before. Canano, however, did not publish what he had discovered or even write it up, but passed on his knowledge of the valves to Vesalius, who made some use of it in the second edition of the "Fabrica" published in 1555. In the first section of his own work, Harvey's concern was not with the valves of the veins but with the respiratory circle, where there are no valves. Having satisfied himself on the essential structure of this circle, he then continued his researches by an investigation of the systemic circle, and so completed his views on the circulation as a whole. In 1616, fourteen years after leaving Padua, he includes in the notes of his three Lumleian Lectures a passage of only eight lines, which, in spite of its brevity, is a clear statement of the circulation of the blood, to which he added the initials WH to indicate that the conclusion was his own. Another twelve years elapse before the idea is finally elaborated in the 1628 work. This prolonged period of gestation of twenty-six years gives but equivocal support to Boyle's description of an interview he had with Harvey in 1663. The great man then stated that it was the structure of the valves of the veins which first suggested "the circular motion of the blood". Harvey himself, however, when studying the history of his thought on the circulation, investigated the valves of the heart but ignored the valves of the veins.

Harvey's methods were simple, but, for his purpose, decisive. For magnification he used only a single hand lens, but this is not surprising since a complete compound microscope is not mentioned in the literature until 1621, and then its performance was less satisfactory than a single biconvex lens, as Leeuwenhoek showed later in the century. Harvey therefore had little knowledge of histology, and he followed Galen in his experimental work and Aristotle in his descriptive and natural history observations. His comparative studies cover an extraordinarily wide field. In the three Lumleian Lectures he mentioned 128 types of animal life, forty-nine in his work on the circulation, and seventy-one in his volume on generation. He emphasizes emphatically that these comparative researches are of vital importance in solving questions presented by the higher animals. He practised vivisection on a large scale, and although he did not invent the ligation method of testing the course of the blood stream, he used it extensively in checking his own views on the circulation. He was always ready to exploit his beliefs by laboratory demonstrations to his friends, and to show them that Nature must be studied by way of experiment. He was therefore prepared to reject tradition when it failed to survive this ordeal. He claimed to be the only one to oppose tradition and to assert "that the blood travelled along a previously unrecognized circular pathway of its own". It must also not be forgotten that Harvey was the first to attack the problem of the circulation by quantitative methods, by which he calculated that the amount of blood discharged continuously from the heart in half an hour amounted to 500 ounces. This could not happen unless the stream moved in a circle. His figures have been condemned as excessive, but it is now known that in violent exercise the result is far greater. Blood capillaries were discovered by Malpighi four years after the death of Harvey, who, however, had already suggested that the finest arterial and venous twigs might be connected up by anastomoses. Harvey could have no knowledge of the oxygenation of the blood in the lungs, but understood that it could only discharge its functions as a fluid motile tissue.

Historians of medicine will be deeply grateful to Prof. Franklin for this learned and accurate translation of Harvey. He now joins the long and imposing list of eminent iatric scholars who have done so much to lighten the labours of their successors. They knew their Latin and were not unacquainted with Greek.

F. J. Cole

GALILEO ON THE PTOLEMAIC AND COPERNICAN SYSTEMS

Dialogue on the Great World Systems

By Galileo Galilei. (In the translation of T. Salusbury. Edited, corrected, annotated, and provided with a Historical Introduction by Prof. Giorgio de Santillana.) Pp. lviii+506. (Chicago, Ill.: University of Chicago Press; London: Cambridge University Press, 1957.) 94*s*. net.

THIS is the first modern English edition of the famous book that was to cause Galileo's conflict with the Inquisition. There exists an older translation by Thomas Salusbury, which appeared in 1661, but which soon became exceedingly rare. Hence the "Dialogue" has remained practically unknown to all English readers who were not able to read it in Italian. The Salusbury translation was very unreliable and obscure. This did not prevent the present editor, Prof. G. de Santillana, from using it as a basis for his own work. Rather than prepare an entirely new translation, he preferred to correct the existing one. It is not at all easy to understand what moved him to this decision. He tells us himself that Salusbury "every few pages . . . takes off on flights of inaccuracy that would make one doubt of his sanity"; he wonders "what the translator would have thought on rereading the nonsense he had written down". Nevertheless, "the Salusbury translation with all its faults, remains better (once corrected) than any modern one could be". This is a remarkable apodictical statement, which in my opinion is disproved at once by the excellent German translation made by E. Strauss in 1891.

However, we have to accept the translator's choice. The more so because the result of his recasting of a bad old translation turns out to be an excellent new one, in which the defects of the former have been put right: it is both correct and clear.

Of course, the text presents its own intrinsic difficulties. Seventeenth-century arguments make no easy reading for a modern scientist. These difficulties, however, are alleviated and to a great extent even removed by a large number of excellent explanatory notes, which are as many proofs of the editor's thorough knowledge of the history of science and of his admirable general erudition. He also provides a historical introduction, in which the deplorable tale of the vicissitudes the "Dialogue" caused its author is succinctly told. It is common knowledge that this subject has been dealt with in greater detail in the editor's recent book, "The Crime of Galileo" (Chicago, 1955). The value of the work is further enhanced by an interesting "Astronomical Note on the Two Systems", by W. D. Stahlman.

The only objection to be raised against this most valuable book is that it is somewhat deficient in references. To begin with, the reader is not told where he might consult the Italian text in a modern version (namely, in the seventh volume of the "Edizione Nazionale") let alone that a concordance with this edition should have been given. There is no list of other editions and translations. The title-page of the original edition is nowhere reproduced. The full title is only given in a footnote to the translator's (that is, Salusbury's) foreword, where it is rendered in an incorrect Salusbury translation. This leads to the regrettable consequence that the reader remains totally ignorant of the original wording of the title and therefore is not in a position to establish that throughout the whole book it is incorrectly rendered. It runs: *Dialogo di Galileo Galilei . . . dove ne i congressi di quattro giornate si discorre sopra i due Massimi Systemi del Mondo, Tolemaico e Copernicano. . . .* It should therefore be translated in an abbreviated form as *Dialogue of Galileo Galilei . . . on the Two Greatest Systems of the World, the Ptolemaic and the Copernican . . .* rather than *Dialogue on the Great World Systems*.

It must be regretted that no list of titles of the books quoted is given and that names of modern authors have been omitted from the index of names. I give one single example. On p. 62, n. 58, the name E. Strauss is given in parentheses. Who, the reader will ask, is E. Strauss and what has he to do with the "Dialogue"? The name is mentioned again on pp. 191, 240 and 284 (this, however, cannot be seen in an index). On the last page mentioned the irritating letters *op. cit.* are added, which only make sense if one can look up somewhere what the *opus* is and where it has been quoted. Finally, on p. 299, the name Strauss occurs again, and it is only here that the reader becomes aware that Strauss made a German translation of the "Dialogue". "Already quoted", the editor says. I must confess that I have not succeeded in finding the quotation; and the reader is still ignorant of the title of the work and the year of publication. Yet the book in question is one of the most important items in the study of the subject. To the same category of bibliographical deficiencies belongs the bad custom often adopted by authors writing in English of quoting works written in foreign languages by an English translation of the title, in which the exact original wording often can scarcely be recognized. This is a deplorable usage. Titles of books are proper names and should be respected as such. They should always be given in the original form, to which an English translation may be added if necessary. Prof. de Santillana, however, quotes Galileo's work "Istoria e Dimostrationi intorno alle Macchie Solari . . ." under the laconic title "Solar Letters". E. J. DIJKSTERHUIS

AIR AND WATER POLLUTION

Air and Water Pollution

The Position in Europe and in the United States. (Project Nos. 136 and 145.) Pp. 218. (Paris: European Productivity Agency of the Organization for European Economic Co-operation; London: H.M. Stationery Office, 1957.) 900 francs; 18s.; 3 dollars.

THIS document consists of the reports of two groups of experts selected from several European countries, including the United Kingdom, to visit the United States to study problems of air pollution (Mission 136) and water pollution (Mission 145). As a first step in 1953, Mission 145 visited industrial and other organizations in western European countries to obtain information on the problems of water pollution in those regions. The group included an expert from the United States, who then expressed the opinion that measures to mitigate water pollution in Europe were similar to those adopted in the United States, where there was little to be seen that had not already been studied by the Mission in the European countries visited. Considerable progress had recently been made, however, in dealing with air pollution in the United States and the developments there would be of interest to European countries, where much remained to be done. Air pollution then became the main study of Mission 136, which spent three months in the United States in 1954.

The first part, on water pollution, occupies about ninety pages and is divided into two main sections dealing with the legislative and with the technical and research aspects both in Europe and the United States. There are also references to international agreements between European countries and between the United States and Canada. On the technical side, there are descriptions of the methods adopted in dealing with polluting waste waters at municipal sewage treatment works and at the many kinds of industrial plants that were visited.

The second part, on air pollution, is similarly divided into two main sections, and there are subsections on the deleterious effects of air pollution on health, agriculture, and materials of construction. In one of four appendixes, there is a selected list of references to 187 publications on the subjects.

In referring on pp. 16 and 17 to experimental work on the Simon Carves–Central Electricity Authority process for removal of sulphur dioxide from chimney flue gases, the statement implies that all the experiments were undertaken at the Fulham power station. The early work was done at the power station, but the experiments with the pilot plants mentioned that led to the multi-stage process of scrubbing with a solution of ammonium salts were all carried out at the Fuel Research Station of the Department of Scientific and Industrial Research. This should have been clear from the original publications to which reference is made.

Another point is that in discussing the disposal of trade waste waters on p. 17, it is said that "where treatment is required to reduce oxygen demand, it is advisable that the effluent involved is passed to the nearest sewage treatment plant possibly during the night when the flow of sewage is at a minimum". In the experience of the reviewer, this is an exceptional method that would probably require a separate tank at the sewage works to receive the discharge during the night for mixing later with the sewage received during the day. The better procedure, and the one usually adopted, is to discharge the trade effluent to the sewer at a rate roughly proportionate to the sewage flow, that is, at a greater rate during the day than during the night so as to assist mixing with the sewage.

Apart from the points mentioned, the document in general is excellent and should be in the libraries of all concerned with problems of water pollution and air pollution. A. PARKER

KINETIC THEORY AND GAS DYNAMICS

Molecular Flow of Gases

By G. N. Patterson. Pp. x+217. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1956.) 60s. net.

IN gas dynamics, four regimes may be distinguished. The first is that of isentropic flow, in which the gas is regarded as a frictionless and adiabatically compressible fluid. Next comes the imperfect fluid regime, in which viscosity and heat conduction are not negligible, and slip and temperature-drop at a wall may need to be taken into account. Then comes a transitional regime, in which the Knudsen number (ratio of free path to a length characteristic of the problem) becomes comparable with unity, as in strong shock-waves or low-density flow. Finally comes the regime of free-molecule flow, in which the Knudsen number is large, and collisions between molecules are unimportant. The first two of these can often be discussed adequately without reference to molecular structure; the others certainly cannot. In view of the increasing recognition of the importance of molecular structure in gas dynamics one is grateful to Prof. G. N. Patterson for a book discussing the effects of this structure in some detail.

The first and third chapters of the book, together with parts of the second and fourth chapters, are devoted to the (mathematical) kinetic theory of gases. Maxwell's velocity-distribution is derived for a simple gas, and Chapman's method is used for deriving expressions for the viscosity and thermal conductivity. Subsidiary topics treated are slip and temperature-drop at walls, bulk viscosity and relaxation effects. The remainder of Chapter 2 is devoted to isentropic motion, which is equated with motion in which Maxwell's velocity-distribution function is valid. An explanation is given of the method of characteristics which is applied to one-dimensional expansion waves and steady two-dimensional flow around the outside of a bend. Chapter 4 discusses non-isentropic flows, particularly in a shock wave and in the boundary layer at a flat plate. The remaining chapter is concerned with momentum and heat transfer in free-molecule flow, and the effect of slip and temperature-discontinuity at a wall in ordinary boundary-layer problems. The Knudsen number is supposed either to be fairly large or fairly small. The transitional regime, in which this number is comparable with unity, is one in which the problems, though interesting, are mostly unsolved, and only one or two allusions are made to them. The treatment throughout the book is mainly mathematical, but there are numerous comparisons with experiment.

The book ranges over an enormous scale of subjects, and attempts to develop most of them from first principles. Inevitably this means that there are omissions and difficulties in the argument, which are sometimes serious when physical explanations are concerned. A reader without previous knowledge could not derive from this book alone a correct idea as to when flow is isentropic, and his ideas on the relation of relaxation processes to bulk viscosity could scarcely be clear. He would certainly wonder how to interpret Fig. 16 on p. 62, and would have great difficulty in ascertaining what problem is being considered in section 5.8. For such reasons as these I wish that the author had tried to cover less, and to spread himself more on the rest.

The book is undeniably stimulating, but to derive full benefit from it one needs to supplement it by further reading, for example, from the numerous papers to which references are given.

T. G. Cowling

VITAMIN A

Vitamin A

By Dr. Thomas Moore. Pp. xx+645. (Amsterdam: Elsevier Publishing Company; London: Cleaver-Hume Press, Ltd.; Princeton, N.J.: D. Van Nostrand Company, Inc., 1957.) 76s.

"In 1915 McCollum and Davis took the initial step in the long journey towards the sub-division of the vitamins by postulating the existence of two factors, Fat-Soluble A and Water-Soluble B." Vitamin A was distinguished from vitamin D a little later, and thus it was found that cod liver oil which had been heated and aerated lost all its anti-xerophthalmic and growth-promoting power, but remained effective in curing rickets. Biological assays, mainly on rats, indicated a very wide distribution of vitamin A-active material in plant products and animal products such as butter, eggs, liver and especially fish-liver oils. An association between yellow colour and vitamin A activity was explored by Steenbock, von Euler and others, and it became clear that the plant pigment carotene was a potent source. Progress in another direction, however, had shown that the vitamin A-active fish-liver oils showed no parallelism between potency as measured by bio-assays and yellow colour. The vitamin A of liver oils was characterized by its ultra-violet absorption and by the blue colour test which it gave with antimony trichloride. In 1929 Dr. Moore himself carried out experiments which elegantly demonstrated that carotene is a precursor of vitamin A, in the sense that ingestion of this highly coloured fat-soluble hydrocarbon by animals deficient in vitamin A results in the appearance of colourless vitamin A in the liver.

Improved analytical methods, mainly spectrophotometric, led quickly to the discovery that some fish-liver oils were very rich sources of vitamin A, and also led to the recognition of a second active material designated vitamin A$_2$ and obtained most readily from the liver oils of certain freshwater fishes. Similarly carotene was sub-divided into α-, β- and γ-isomers. Organic chemists, led by Karrer, Heilbron and others, established the structures of the carotene isomers and of vitamin A$_1$ and that of vitamin A$_2$ followed after a considerable interval. It is possible to-day to purchase synthetic pure β-carotene and vitamin A at very reasonable prices. Behind this is remarkable technical achievement in which Isler played a big part.

The past thirty years have seen the fish-liver oil industry, once concerned only with cod, extended to halibut, shark and tunny and many other species. This expansion has served the general welfare by providing vitamin oils for human and animal prophylaxis. Synthetic vitamin A and carotene are added to margarine to the levels found in good butter. The part played by vitamins A and their aldehydes, retinene$_1$ and retinene$_2$, in the formation of visual pigments has become fairly clear but much less is known concerning the systemic mode of action of vitamin A.

The literature concerning this vitamin is now very large, but Dr. Moore's book is admirably selective. The chemistry of provitamins and vitamins A and various analytical problems are adequately described, and the author's experience and judgment are seen to great advantage in a very thorough discussion of the physiology and biochemistry of vitamin A and its provitamins. This section covers absorption, storage, mobilization and transfer from mother to offspring, as well as biological activity in relation to structure. Another section deals with the pathology of vitamin A deficiency or excess. This is followed by a long but very well-planned review of vitamin A in man. Chapters are devoted to special topics such as vitamin A in relation to sex, and vitamin A and the thyroid. The final chapter consists of a shrewd assessment of our present knowledge of vitamin A. This is followed by a number of useful appendixes.

This book must at once take its place as the standard work on a subject with many ramifications. The presentation is lucid, and the author does not lose sight of the fact that his readers will differ greatly in training and interests. Dr. Moore has tried earnestly to recognize 'the originator of every important discovery' in the field and in this task he has demonstrated fairness and sound scholarship. The book is illustrated with well-chosen photographs and diagrams, and each section is fully documented. Research workers interested in vitamin A from almost any angle will find in Dr. Moore a safe guide to the frontier of knowledge. He does not often venture far over the frontier, but the urge to do so can often be read between the lines of the restrained and modest narrative.

R. A. Morton

The Mechanism of Phase Transformation in Metals

A Symposium organized by the Institute of Metals and held at the Royal Institution, London, on 9 November 1955. (Institute of Metals Monograph and Report Series, No. 18.) Pp. iv + 346 + 45 plates. (London: The Institute of Metals, 1956.) 50*s*.; 7.50 dollars.

DETAILS of the phase equilibria occurring in alloys represent a major foundation metal theory. The more difficult task is not so much to determine the actual phase conditions at equilibrium, but rather the mechanism of transformation from one set of conditions to another. In particular, it is the formation of various metastable products, *en route* to equilibrium or under conditions that do not allow the normal path to be followed, that provides such a diverse field of behaviour for investigation.

The present monograph is valuable because it gives in one volume a satisfactory summary of knowledge to date, which should prove useful not only to those with specific interest in the mechanism of phase transformations, but also for those who merely wish to keep up to date in a general way. The treatment has been classified broadly under two headings: first, those changes following a nucleation and growth sequence; and secondly, martensitic transformations involving, in contrast, a co-operative movement of the atoms. In each case a lengthy general review is followed by a number of shorter and more specific papers. Finally, there are more than sixty pages of general discussion. The matter is of high standard and forms a sound and stimulating account.

A. R. Bailey

Records and Research in Engineering and Industrial Science

By Dr. J. Edwin Holmstrom. Third edition, re-written and enlarged. Pp. xii + 491. (London: Chapman and Hall, Ltd., 1956.) 60*s*. net.

UNCHANGED in title and in theme, the third edition of Dr. Holmstrom's book has been so substantially enlarged, re-arranged and re-written that it could reasonably be described as a new book. One chapter, dealing with the technician as a person, has been discarded, but neither in title nor in content are the nine that remain, apart possibly from the first, at all comparable with those in the second edition. The first chapter, in which Dr. Holmstrom discusses the nature and methods of technical science, illustrates one of the features in which the third edition constitutes a marked improvement on the earlier editions. It is characterized by a representative selection of references to outstanding post-war writings on this theme, and some thirty of the hundred odd additional pages of the new edition are occupied by an excellent bibliography. Dr. Holmstrom's reading is encyclopædic, but although he makes no claim to comprehensiveness, the basis of his selections either in time or in extent is not obvious and may be misleading to a reader. It is puzzling to find, for example, the "Dictionary of Applied Physics" and Kirk and Othman's "Encyclopedia of Chemical Technology" included, but not the "Dictionary of Applied Chemistry". Again, his references to organizations in the United States are strikingly incomplete in respect of publications of the past year or so, within which period he has given other references that might well have been too late to be included. There are also some surprising omissions in his account of organizations in other countries—for example, the National Foundation for Scientific Research, Brussels, and the Institute for Scientific Research in Central Africa. The book has been so greatly improved both bibliographically and in treatment of post-war developments that it would be a pity if readers were led to attribute to it a comprehensiveness to which the author himself makes no pretence.

R. Brightman

Realities of Space Travel

Selected Papers of the British Interplanetary Society. Edited by L. J. Carter. Pp. 431 + 23 plates. (London: Putnam and Co., Ltd., 1957.) 35*s*. net.

AS part of its activities, the British Interplanetary Society publishes a journal containing articles relating to space-travel. A number of those which have appeared since 1948 have been collected in a single volume under the editorship of the secretary of the Society. The compilation forms an excellent introduction to various aspects of extra-terrestrial flight which should be understandable to anybody with some knowledge of elementary mathematics and physics.

Escape from the Earth's gravitational field, the dynamics of propulsion and certain aspects of orbit theory are fully treated. The problem of navigation is regrettably ignored.

Detailed designs of vehicles which might be used are rightly not presented. Attention is instead confined to basic features, such as rocket motors and wings for braking in descending through an atmosphere. The concentration on the question of what is possible in principle is to be commended. However, it might have been desirable to consider the extent of the practical engineering difficulties that would be encountered in the assembly of the satellite stations proposed by von Pirquet, in landing on and taking off from the Moon, or in one of the other major projects envisaged.

The survey is completed by interesting contributions on the following: instrumented satellites; meteor and cosmic ray hazards; physiological effects; air, water and food supplies for a voyage; conditions on neighbouring worlds.

There are numerous informative figures and tables and the general production is of a high standard.

D. R. Bates

Introduction to Structure in Organic Chemistry

By Prof. C. K. Ingold. Pp. vii + 200. (London: G. Bell and Sons, Ltd., 1956.) 20*s*. net.

THE present volume consists of the first four chapters of Prof. Ingold's larger work, "Structure and Mechanism in Organic Chemistry" (1953). Dr. W. A. Waters, in a highly commendatory review of this earlier book (*Nature*, 173, 278; 1954), called it a "classic of scholarship". Chapter 1 deals with covalency, its physical interpretation and electronic character, and with the interpretation of stereochemical form; Chapter 2 with interactions between non-reacting molecules, and also with intramolecular interaction, its significance and its internal transmission; Chapter 3 with electric dipole moments, and with the physical properties of molecules; Chapter 4 with the theory of aromatic character, and with the diamagnetic and other physical properties of the aromatic nucleus. The book is therefore essentially an exposition of the general principles of molecular structure with all the illustrations taken from organic chemistry.

G. Fowles

THE THREE TYPES OF EVOLUTIONARY PROCESS

By Dr. JULIAN HUXLEY, F.R.S.

THE three major types of process operating in evolution are those leading to divergence and variety, to adaptedness and biological improvement, and to stabilization and persistence of type. Darwin[1] before 1859 had realized the universality of the first two processes, and had noted some examples of the third, the importance and widespread occurrence of which was stressed by T. H. Huxley[2] in 1862. However, from then on to the end of the century most biologists were concerned with establishing the fact of evolution and the evolutionary interpretation of comparative anatomy, taxonomy and adaptation; while the period 1900–30 was chiefly devoted to establishing the mechanism of evolution–natural selection on the basis of particulate variation and inheritance. Only since then has attention been focused on evolutionary process.

The time has now come to define the three major types of evolutionary process more strictly. I accordingly propose the terms *cladogenesis*, *anagenesis*, and *stasigenesis* for the processes leading to divergence, improvement, and persistence respectively. *Cladogenesis* I have taken over directly from Rensch[3], to denote all splitting, from subspeciation through adaptive radiation to the divergence of phyla and kingdoms. Rensch[3] has used *anagenesis* to denote advance in general organization or perfection of some major function: I propose to generalize it to cover all types or degrees of biological improvement, from detailed adaptation to general organizational advance. The universality of persistence has not been properly recognized: I therefore propose the term *stasigenesis* to cover all processes leading to stabilization and persistence of types and of patterns of organization, from species up to phyla.

In passing, evolutionary biology is also handicapped by the absence of a suitable chronological terminology. We still specify evolutionary time in terms of millions or hundreds of millions of years. This is as inadequate as if we were forced to describe individual human age in terms of millions of seconds, or human history in terms of hundreds of millions of minutes. I therefore suggest the term *cron*, simplified from χρόνος, to denote 1 million years as the basic unit of evolutionary time, with derivatives such as *kilocron* for 10^9 years and *millicron* for a millennium.

The result of evolution has been to produce a number of delimitable taxa or recognizably distinct groups of organisms, each characterized by a particular pattern of organization, which can be further grouped in a hierarchical arrangement—species, genera, families, orders, classes, and phyla. When fossil evidence is available, taxa, notably those of larger extent, often show succession and replacement, a once abundant group becoming replaced in its successful evolutionary position by a later group, often one to which it has itself given rise. The replacement may either be total, eventually involving extinction as well as reduction, like that of the *Archaeornithes* and the toothed birds by modern birds, or partial, involving only reduction, like that of Reptilia by Aves and Mammalia. The earlier group may show extreme reduction, only a few 'living fossils' surviving, as with *Dipnoi*, *Limulus*, *Nautilus* and the recently discovered archimollusc *Neopilina*[4].

Almost always the reduced group persists for a considerable time, and often indefinitely, after the emergence of the new and more successful group. Furthermore, even the latest-evolved and most successful (dominant) groups show stabilization and persistence through tens of crons within certain defined organizational limits; for example, Aves since the Miocene, and Formicoidia since at least the Oligocene.

Here we see stasigenesis at work. Evolutionary success appears to depend on the acquisition of an integrated plan of organization, which shows evolutionary homoeostasis or stability in confining variation within the limits of its general pattern. Only in exceptional circumstances will the emergence of a new stabilized pattern be possible. This applies at all levels. Mayr[5] has shown that it applies at the species-level. In the 'explosive' period of a group's evolutionary radiation, many divergent subgroups are produced, only the better integrated adaptive types surviving[6]. At still higher levels, a successful group like the Reptilia produced a major radiation of types, but almost all remained within the reptilian pattern: only two lineages, those leading to Aves and Mammalia, achieved a new stabilized organizational pattern capable of showing further major radiation.

Intrinsic restrictions, depending on inherent properties, may also operate to set an upper limit to the range of evolutionary variation possible to a group: for example, size and speed in crustaceans, insects and terrestrial vertebrates; visual performance in vertebrates, arthropods, etc. Only when the unique

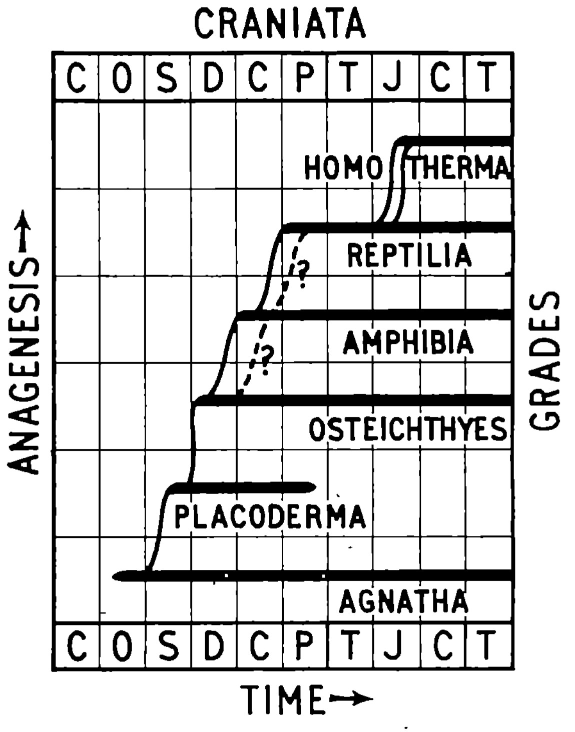

Fig. 1. Anagenesis and stasigenesis in vertebrates, leading to a succession of persistent grades. *T*, Tertiary era: other initials indicate geological periods from Cambrian to Cretaceous

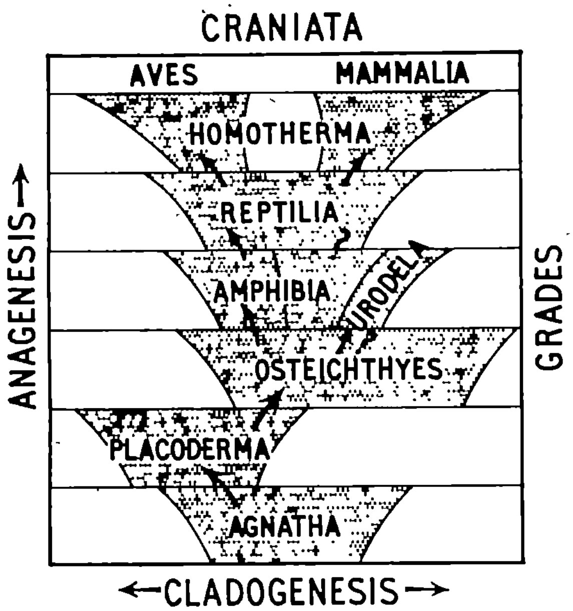

Fig. 2. Anagenesis and cladogenesis in vertebrates, with time eliminated. Some grades are also clades (monophyletic), others possibly or certainly diphyletic

emergence of man had made possible exosomatic evolution, and with it new materials and new types of organization, could these limits be transcended.

Anagenesis also operates at all levels to produce the improvement of evolutionary trends of every scale. As Darwin clearly stated[1], natural selection inevitably promotes biological improvement, but always "in relation to the conditions of life". Thus the description and analysis of anagenesis must always be relative to the scale and nature of the particular trend under consideration, whether detailed adaptation to a specific niche, specialization for a particular mode of life, advance in efficiency of a major function such as hearing or homoeostatic regulation, advance in general organizational level, or progress in the sense of advance which does not stand in the way of further advance[7]. The reduction or loss of certain organs can properly be called anagenetic in respect of specialization for a particular mode of life: for example, the loss of digits in higher ungulates or the 'degeneration' or loss of organs in certain parasites.

What I have called 'advance' and 'progress' may be measured or at least estimated by increase in control over environment and in independence of environmental change[7]. We may require special technical terms for improvements of different scale and relevance, such as 'advance', 'progress', etc.; here I am only concerned to point out the need for a single term to cover all types of improvement.

Cladogenesis operates primarily by a combination of isolation and natural selection, with occasional contributions from drift and similar genetic phenomena. The increased variety which it generates is itself from one point of view an anagenetic improvement, since (as Darwin, also clearly pointed out) it permits a fuller exploitation of the environment.

All three processes co-operate in evolutionary phenomena of all scales from the species-level upwards. Cladogenesis results in the formation of delimitable monophyletic units, which may be called *clades*; and anagenesis results in trends of improvement. But cladogenesis always involves some degree of improvement (anagenesis): this is most obvious in adaptive radiations which produce many specialized lines, but occurs also in divergent species, which are always to some extent adaptively differentiated. Finally, stasigenesis results in the formation of delimitable and persistent anagenetic units, or *grades*, as is obvious when anagenetic improvement is plotted against time (Fig. 1). Most delimitable taxa will thus be simultaneously both clades and grades: on a two-way graph with time eliminated and anagenetic improvement plotted against cladogenetic divergence (Fig. 2), they will appear as *evolutionary areas*, and the direction of evolutionary trends will almost always be oblique, the resultant of cladogenetic and anagenetic processes in combination.

In point of fact, taxa are usually recognized as grades which have been observably delimited by the fact of their stasigenetic persistence. Save in the exceptional event of abundant fossil evidence, phylogeny is not observable and must be deduced, so that the phylogenetic relationships of taxa are much more speculative. Unfortunately, however, since "the avowed aim of a modern classification is to reflect phylogeny" in which "the categories are monophyletic"[6], the conscious or more often unconscious assumption behind most systems of classification is that named taxa are or should be monophyletic clades, even though in their work taxonomists often adopt more pragmatic methods[8]. In practice, however, a number of named taxa have turned out to be certainly or probably polyphyletic (for example, the 'subkingdom' Metazoa, the 'phylum' Bryozoa, the 'order' Teleostei[4], the 'family' Miacidae, the 'genus' Merychippus): they are grades, but not clades.

In general, the implications of the three co-operating processes of evolution have not been made explicit, and the fact that anagenesis and stasigenesis in combination produce delimitable gradal units has not been fully taken into account.

Taxonomy will have to envisage a two-way system of classification, which will do justice to the facts of biological improvement and persistence of types as well as to those of phylogenetic divergence[9]. Such a system must recognize that many delimitable taxa are simultaneously grades and clades, and that others are grades which may or may not also be single clades. This will presumably involve some new terminology, though not necessarily subject to the international rules of nomenclature. Some new purely gradal terms will be required: for example, Homotherma for Aves plus Mammalia, and Psychozoa for man. This last example is illuminating. Cladogenetically man constitutes only the single family Hominidae: but anagenetically he constitutes a grade equivalent in evolutionary importance to all other organisms taken together.

SHORTENING OF LIFE BY CHRONIC IRRADIATION: THE EXPERIMENTAL FACTS

By R. H. MOLE

Medical Research Council Radiobiological Research Unit, Atomic Energy Research Establishment, Harwell, Berks

IT is probably true to say that more is known of the biological effects of radiation than of any other environmental hazard except bacteria. Certainly the chronic toxicity of no chemical substance has been investigated as thoroughly as the chronic toxicity of whole-body irradiation by penetrating gamma-rays or fast neutrons. The incentive has been obvious: the very large industrial hazard during the war-time development of the atom bomb, and afterwards the increasingly widespread risk associated with the remarkable development of atomic energy as a source of industrial power and of a unique series of military weapons. Chronic toxicity experiments in the strict sense must cover the whole life-span of the experimental animal and thus take years to carry out, even with the relatively short-lived laboratory mouse. The results of war-time work in the United States have become generally accessible in the past few years[1-5] and work carried out in this laboratory is just beginning to be published[6]. A brief survey of the experimental results relating to shortening of the life-span may provide a few facts in a field of current general interest and perhaps raise the academic question of how the results of chronic toxicity experiments, as such, may be generalized—a question which needs an answer before they may be used to help solve the practical problem of setting safe limits to the environmental exposure of man to irradiation.

Experimental Methods

Daily irradiation has been given to animals in a variety of ways, for details of which the original reports should be consulted[1-7]. The more important experimental features are summarized in Table 1. There were two important differences between the experimental arrangements of Henshaw *et al.*[3] and Evans[2] on one hand, and those of Lorenz *et al.*[4] and of this laboratory on the other. In the first two sets of experiments, the animals had to be transferred individually each day from their living cages to the irradiation boxes and back again, and each daily dose of radiation was given in a few minutes. In the second two sets of experiments, the animals were irradiated in their living cages, undisturbed by additional handling with its accompanying traumatic effects, and the daily dose of radiation was spread over 8–24 hr. In general, the experimental animals were examined daily and the time of death noted. Post-mortem examinations to determine tumour incidence and the cause of death were usually made, but the experimental reports differ very greatly in the detail with which these findings are given. For this reason, and since shortening of life-span is often considered the most sensitive experimental index of the toxicity of chronic irradiation, survival-time is the only experimental end-point considered here.

Results and their Interpretation

By chronic irradiation is meant daily irradiation 5, 6 or 7 days a week at dose-levels which allow survival for at least six months. All the experiments on chronic irradiation for the duration of life which have ever been carried out, so far as is known, are referred to in Table 1 and, where possible, shown in Fig. 1. The duration of life of an irradiated group of animals has been expressed as a proportion of its corresponding control and plotted against the weekly dose of radiation on a logarithmic scale. The results from this laboratory are shown in black symbols. They provide the first direct experimental comparison between gamma-rays and fast neutrons for chronic irradiation, where the dose of fast neutrons was measured in terms of energy absorbed in tissue. The relative biological efficiency factor for the fast neutrons used as compared with cobalt gamma-rays was 13.

This factor has been applied to the other two fast-neutron experiments, where the fast-neutron dose was measured in arbitrary units and where a somewhat uncertain conversion factor (Table 1) has to be used for estimating the tissue dose. In this way the results of all the experiments with fast neutrons as well as those with gamma-rays from other laboratories have been plotted, using open symbols, together with our own results in Fig. 1. The agreement, when mice were used as experimental animals, is remarkable, and suggests, in spite of the various uncertainties in the comparisons, that chronic irradiation shortens the life of mice in a reproducible manner.

It should be noted that there are eight experimental points at weekly doses of less than 10 r. or its equivalent in neutrons, and that the duration of life

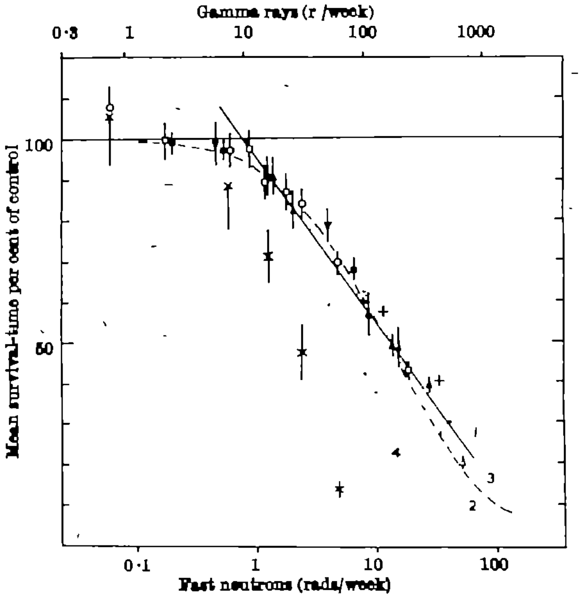

Fig. 1. Mean survival-time (per cent of control) and weekly dose of radiation (logarithmic scale)
The symbols are given in Table 1. The curves are numbered as in the text, where they are discussed. The gamma and neutron scales are in the ratio 13 : 1 (see text)

* Mean survival times calculated from data provided by Hollaender and Stapleton (1948, personal communication) have been used in Fig. 1.

† Mean survival-time of the two strains combined were also reported and have been used in Fig. 1 because standard errors were also given. However, irradiation stopped when 8–30 per cent of an experimental group was still alive, so that the mean survival times include variable proportions of radiation-free time.

‡ There were real sex differences in control life-span and possibly also in the effects of irradiation. The data have been pooled to make them comparable with those of the other authors.

The data of Henshaw (ref. 7) have not been included because the mean life-span of his controls was less than a year. The data of Boche (ref. 1) have not been included for a variety of reasons: his monkeys had tuberculosis, his mice salmonellosis; the dogs and rabbits were irradiated in small numbers and irradiation stopped after two years, long before the end of the natural life-span; irradiation of the rats also ceased after two years when 16–36 per cent of the lower level and control groups were still alive and were killed, which prevents estimation of mean survival-times.

Evans's X-ray data (ref. 2) have not been included because mean survival-times were not given. The control life-span was not given by Hagen and Simmons (ref. 5). In each of Sacher's (ref. 5) and Mole's (ref. 11) experiments with daily X-irradiation of mice, one experimental group survived about seven months; they are omitted because no groups surviving longer are available and because the relative biological efficiency for X- to gamma-rays for chronic irradiation is not known.

in none of these experimental groups was significantly different ($P > 0{\cdot}05$) from its control.

The experimental results have been put down as they were obtained. More sophisticated analyses of some of these results have been made elsewhere[1,5,6,9,10]. The purpose of such analyses has usually been to find some regularity in the results which would allow extrapolations to daily doses smaller than, and to species other than, those used experimentally.

Curve Fitting

Three curves have been fitted to the mouse data and are shown in Fig. 1.

(1) The straight line which provided the relative biological efficiency factor of 13 from our second experiment (Neary *et al.*, II, Table 1) is clearly a good fit to its results, and is also reasonably close to the only experimental group in our first experiment with a markedly decreased survival-time. The simplest interpretation of such a linear relation is that there is a threshold of between 1 and 2 r. daily below which no shortening of a mouse's life will be produced by daily irradiation. This may be considered confirmed by the repeated experimental failure to find a demonstrable shortening at weekly doses of less than 10 r. (see above). Considering the nature of the data, it would be difficult to have a clearer experimental demonstration of the existence of a threshold.

(2) The biologist, almost as a reflex, attempts to fit a Gaussian curve to quantitative data. Such a curve is shown as a dashed line in Fig. 1, and clearly fits all the experimental data very well. The meaning of the fit at weekly doses of less than 10 r., where none of the points differs significantly from the base line, is less clear.

(3) Boche (1946, 1954)[1] suggested that shortening of life-span was proportional to the total accumulated dose,

$$t - t_0 = kdt$$

where t and t_0 were the mean life-spans of irradiated and control animals, d was the daily dose of radiation and k was a constant. This curve ($k = -0{\cdot}04$ for gamma-rays) is shown in Fig. 1 as a dotted line, which also fits all the experimental points very well.

Curves 1 and 2 are empirical; curve 3 has some claim to a theoretical basis, the idea that the bigger the total dose of radiation the bigger the effect, that is, the shorter the mean life-span. For daily exposures which kill in less than six months, however, the converse is found to be true[4,9,11]. This is not as paradoxical as it may seem, once the importance of recovery processes is appreciated; but it makes data on the effects of high daily doses (on shortening of life by much more than 50 per cent) of little value in helping to decide which is the best of several curves, each purporting to describe the effects of low daily doses.

Curves 2 and 3 are clearly so close together that over the experimentally determined range they cannot be distinguished. (The possibility that this algebraic similarity has a much wider biological significance is being investigated.) Each curve appears to fit all the points better than the straight line of curve 1, but this may be a spurious consequence of experimental uncertainties. In two experiments the exact conversion factor from arbitrary units of fast neutrons to rads is unknown (see above) and factors numerically different from those used (Table 1) but just as plausible (see literature) would make the fit look less good. There seems to be no intrinsic reason why different mouse strains *should* behave identically, and the curvilinear arrangement of the experimental points may merely reflect differences of strain and of dose.

Each of the second two formulations indicates that there is no absolute threshold for shortening of life by chronic irradiation. The apparent threshold suggested by curve 1 may be thought of either as an absolute or as an effective threshold, depending on whether shortening of life is considered in proportional or absolute terms. If time is necessary for the effects of daily irradiation to show themselves, and if this time is longer the lower the daily dose, then an effective threshold *must* be reached at a dose-level which takes longer than the life-span to produce its effect. If so, each species would be expected to have its own threshold, and the longer the natural life-span the lower this would be. The only relevant experimental data are those of Lorenz *et al.*[4] on chronic irradiation of guinea pigs and these are included in Fig. 1. The effect of 1·1 r. daily was possibly greater than in mice (though still not significantly different from its control) and the apparent threshold possibly a little less. The difference in life-span between mice and guinea pigs is probably not large enough to decide the point, and in any event there are no confirmatory data for guinea pigs as there are for mice.

The data for guinea pigs do show that species differences occur. Boche[1] suggested, on admittedly tenuous evidence, that the constant k (curve 3) is αt_0, where α is the same for all mammals. If this were true, the mouse data should not agree so well, since t_0 for the different mouse strains differed. If the mean mouse t_0 is 600 days, $\alpha = 7 \times 10^{-4}$ (rather different from Boche's own estimate), and this has been used to construct the theoretical curve for guinea pigs ($\alpha t_0 = -0·09$, curve 4, Fig. 1); the fit to the experimental points is poor.

Nature of the Experimental Material

In any event, too much should not be read into the results because of the nature of the experimental material. First, the results have all been expressed in terms of mean survival-times. This is really a rather unsatisfactory parameter to use, as may be seen from Fig. 2, which illustrates the shape of the mortality curve of normal control female *CBA* mice. The shape of the human mortality curve in the more materially advanced human civilizations is similar, but that of mice with a high spontaneous incidence of leukaemia may be very different[4,12]. The mean survival-time and its statistics are markedly affected by the occasional early deaths and no great precision in mean survival-time can be expected. A small decrease in mean survival-time could occur either because of a small increase in the frequency of earlier deaths or because of a small reduction in life-span of the upper two quartiles. In fact, an analysis of cause of death in relation to duration of life is imperative in order to see whether irradiation decreases life-span by increasing the frequency of particular causes of death which kill earlier than the average, or merely by making all causes of death kill at an earlier age[9].

Second, the nature of a chronic toxicity experiment usually, if not invariably, makes it impossible to randomize treatments and to ensure that the only difference between experimental groups is the treatment being investigated. For example, if animals are arranged at different distances from a source of radiation, the animals will occupy different parts of a room for their whole lives and it will be impossible to be sure that environmental temperature, humidity, degree of air movement and other relevant factors possibly not even thought of, are exactly the same for each different dose-group. Thus the differences in, say, mean survival-time between different groups will be due to the differences in radiation-level plus any other relevant environmental differences. This is not just a theoretical point. Differences of the order of 5 per cent in the mean survival-time of female *CBA* mice have been found during the past few years not only between different 'lots' of controls but also between two sets of randomly chosen controls kept, so far as could be, in the same environment but some 20 ft. away from each other[9]. The apparent increase in survival-time at the lowest daily dose used by Lorenz *et al.*[4] (Fig. 1) may well be due to the fact that the animals at this dose-level were kept without air conditioning in a different room from all the other groups, including the controls. Such variability is to be expected by the biologist, but it should also enjoin caution in extrapolation of the results of analysis of intrinsically inexact data.

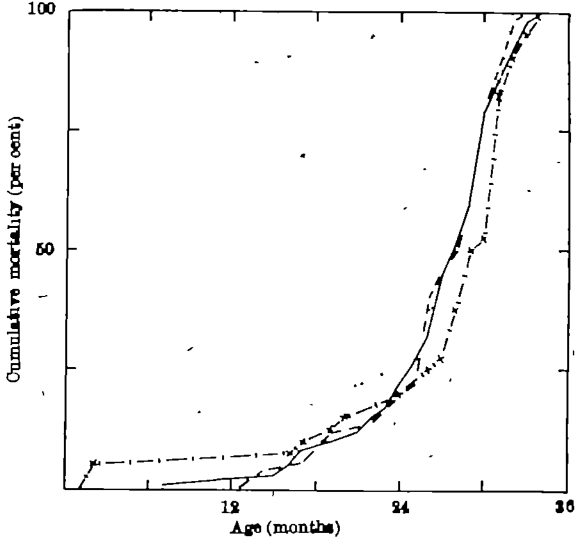

Fig. 2. Cumulative mortality of female *CBA* mice (four different control groups 1951–54). All times plotted from same starting age of 70 days

Replication on a sufficiently large scale, though often completely impractical, could overcome this particular difficulty. In fact, however, replication is almost completely lacking from the experiments listed in Table 1. The logic of experimentation is that experiments are repeated and give the same result. Yet with the exception of a still unfinished investigation[16], no one concerned with duration-of-life irradiation experiments has ever repeated his experiment even once—for which there are perhaps understandable reasons. The nearest to repetition so far has been the two experiments carried out in this laboratory[4,15], where although the same mouse strain was used the radiation doses were different. From this point of view the value of Fig. 1 is to demonstrate that an experiment has been done, that is, that the same result has been obtained several times over.

Lastly, it should be pointed out that in all the experiments considered here irradiation has been for the duration of life. This may not be the most appropriate experiment to carry out. Recent[9,14,15], as well as older[4,16], evidence has shown that, in some circumstances at least, not all radiation is of equal value, the first of a series of daily doses having proportionately greater effects in shortening life and inducing leukæmia than the later daily doses. This is presumably one aspect of the time factor; time is needed for the effects of irradiation to develop to the point where biological damage can be detected[11,14,17], and/or the reactivity of the biological object may change with age[11]. But if the phenomenon is true of weekly doses of less than 50 r., which has not yet been demonstrated, formulæ which give equal weight to each of a series of doses, as Boche's, cannot be properly extrapolated. Further, if at relatively high daily doses much of the radiation is wasted, so far as producing an effect is concerned[11], then an observed linearity of response against total dose (curve 3, Fig. 1) may imply a decreasing ability of radiation to harm as the daily dose decreased.

There has also been very little work yet on the problem of whether the effect of chronic irradiation is altered by changing the distribution in time of, say, a constant weekly dose. The data of Table 1 and Fig. 1 suggest that it matters little whether a daily dose is given in a few minutes or spread out over many hours; but other as yet uncompleted observations[14,17] suggest that the delayed effects of irradiation may depend as much on the way the irradiation is given as on the total dose. In these experiments there was no wasted radiation: on the contrary, as much time as possible was allowed for the full development of any damage that radiation may have caused. Such experiments may give a relation between shortening of life and dose of radiation very different from those shown in Fig. 1, and indeed this might well be anticipated by anyone aware of the normal complexity of biological phenomena. Dose–response curves should not be extrapolated without fully realizing the nature of the experimental material on which they are founded.

Possibilities of Extrapolation

It should first be emphasized how unusual it is to pay any attention to the ends of a biological dose–response curve. Normally, the aim of the biologist is to work in the middle ranges and, if irregularities appear at the ends, this is regarded as just to be expected, not necessarily deserving investigation.

The current maximum permissible level of radiation for occupational exposure of man, 0·3 r. weekly (Recommendations of the International Commission on Radiological Protection), is indicated in Fig. 1. Extrapolation suggests that this dose-level would shorten the lives of mice by nil, 0·02 or 0·2 per cent, depending on which of the three curves described earlier is taken to be correct. As already shown, the experimental data on chronic irradiation at low doses are not sufficiently exact to distinguish between the curves, and the adequacy of fit at high levels of irradiation seems quite irrelevant. Thus the value of any attempt at extrapolation must depend on whether there is some theoretical reason for preferring one mathematical form to another. When this question is settled, there is the additional problem of extrapolating from one species to another.

One principle of selection often used nowadays in general discussion on radiation as it affects mankind, and at first sight self-evidently sound, is to take the most pessimistic assumption suggested by experiment or theory for the relation between dose and effect. Lorenz[8] used a very similar criterion when discussing the effects of daily irradiation on the different tissues and organs of different species. He concluded that man should be considered to be as sensitive as that species of animal found experimentally to be the most sensitive. Clearly this is no absolute criterion as the range of species examined is widened, the apparent sensitivity of man must decrease. A consistent use of this criterion would involve denying the possibility of chemotherapy, or of selective killing by pesticides. It does not seem realistic to maximize pessimism as a means of choosing the best dose–response curve.

The most plausible reason for thinking that species differences among mammals in their reactions to irradiation are likely to be smaller than in their reactions to chemical agents is that the penetration of radiation into cells is not affected by the series of permeability barriers which every chemical agent has to pass before reaching the site of its action[18]. The uniformity of the acutely killing dose for all mammals gives supporting evidence. However, the chronic toxicity of radiation would be expected to depend on a balance between the continuing damage produced by the radiation and the ability of the irradiated animal to keep pace with the damage by repair. The ability to repair and its rate must depend on many of the structural and metabolic features which distinguish strains and species, and, for this reason, strain and species differences in the dose–response curves for chronic irradiation might be expected. Some of the experimental facts can best be understood in this way[8].

An alternative view is to assume that the chronic toxicity of radiation is due to processes where repair of damage does not occur, like genetic mutation. It may then be plausibly argued that the genetic material of all mammals is very similar, both physically and chemically, and that therefore dose–response curves will in general be the same for all species. Such a view would suggest that damage should be proportional to total dose, as in Boche's formula (curve 3, Fig. 1), and would be consistent with the somatic mutation theory of carcinogenesis and the fact of carcinogenesis by ionizing radiation. But there are difficulties in the way of equating damage and total dose, as already suggested, and really very little evidence in support of the mutation theory of carcinogenesis. The theory is an easy one to accept; but even with the most recent advances in technique its testing seems almost impossible to envisage. However, in the experimental animal there is no simple relation between carcinogenesis and dose of radiation, and for mouse leukæmia there is good evidence of the great importance of an indirect mechanism[19]. Moreover, the experimental evidence suggests that radiation shortens life apart from inducing cancer, and this is not easy to understand in terms of mutation.

If the results of animal experiments are to be carried over to man, there must either be very good evidence that all mammals behave alike, or sufficient human evidence of similarity with experimental animals to inspire confidence in the process of filling the human gaps from animal experience. It will at least be generally agreed that experimental dose–

response relations which cannot satisfactorily account for all experimental results are scarcely worth applying to the human case. In the absence of a satisfactory theory, it seems pointless to expend the enormous experimental effort required to define the relation between daily dose and life-span for mean survival-times of 95 per cent and more of the control: it is only in this region that extrapolation to man is of any particular interest.

I would like to thank my colleagues for allowing me to make use of unpublished material.

LOW-TEMPERATURE PHYSICS IN THE U.S.S.R.

THE fourth Russian conference on low-temperature physics was held during July 2–8 at the Institute for Physical Problems of the Soviet Academy of Sciences in Moscow. Six physicists from Great Britain, Drs. R. G. Chambers, H. A. Hall and A. B. Pippard from Cambridge, and Drs. R. Berman, A. H. Cooke and the author from Oxford, were invited to this meeting as guests of the Academy and were the only foreign visitors.

Since this was the first meeting with Russian low-temperature workers, a brief enumeration of the Soviet cryogenic research centres may be of interest. There are two laboratories in Moscow, since, besides the Institute of the Academy, there is also a cryogenic research team under A. I. Shalnikov working at the University. Kapitza is the director of the Institute for Physical Problems, but in the past two years he has devoted himself to other than low-temperature research. Peshkov is the deputy director and Molkov is in charge of the section dealing with cryogenic engineering. Another section, in a separate building, carries out research into the electronic behaviour of metals and is in the charge of Alekseevsky. Also at the Institute there is a theoretical physics section of which Landau is the head and in which E. M. Lifshitz and Khalatnikov are senior members. Kharkov has an old-established cryogenic laboratory, with Lazarev as director and I. M. Lifshitz and Kaganov as theoreticians. Of more recent date is the low-temperature laboratory at Tiflis, which is under the direction of Andronikashvili. There is another new cryogenic laboratory in Sverdlovsk.

At the conference, papers and discussions, except those by the visitors, were given in Russian; but the visitors were supplied with headphones and a simultaneous translation was provided for them. For this translation Kapitza had obtained the services of Mr. Boris Belitzky, of Moscow Radio, who is a physico-chemist by training. Mr. Belitzky's truly amazing gift for rendering not only the lectures but also the—often heated—arguments accurately into faultless English made all the difference to the success of the meetings so far as we were concerned. He clearly lived the part of the speakers, and the visitors came to forget that the voice they heard was not that of the lecturer. Judging from adverse reports on similar meetings, the value of a really good interpreter cannot be assessed too highly at a conference of this type. We were able to follow the proceedings so completely that a whole week of lectures in Russian never became tedious.

The following brief summary of the papers presented at the conference cannot give any details of the experimental results or the theoretical investigations which were reported. Its object is to give an idea of the type of research in progress in the U.S.S.R. and to provide a list of the work done by the various authors so that interested readers can apply to them for reprints or further information*.

After an opening address by Kapitza, the conference began with a series of papers on liquid helium which occupied two sessions. Much of the work was concerned with the light isotope and with isotope mixtures. The viscosity of pure liquid helium-3 has been measured between 0·35° and 3·2° K. by Miss K. N. Zinovieva, who works in Peshkov's laboratory. She reported a sharp rise of the viscosity with falling temperature below 1° K. which, however, at the lowest measured temperature has not yet reached the theoretically predicted value of T^{-2}. Above 1° K. a slight drop in viscosity with rising temperature is in qualitative agreement with the theory of Abrikosov and Khalatnikov. It is interesting to note that she also found a slight drop in the viscosity of helium-4 above 2·6° K. instead of the slight rise with temperature reported by Bowers and the present author seven years ago. She ascribed (correctly) this discrepancy to the omission of a correction in our work. Miss T. P. Ptukha, working in the same laboratory, presented measurements of the density of mixtures of liquid helium-3 and helium-4 and deduced lambda temperatures for four concentrations from the break in the density curves. The Kharkov workers, B. N. Esselson, A. D. Shvets and R. A.

---

Bablidze, have determined the lambda points of mixtures of helium-3 and helium-4 by the onset of film flow. An interesting theoretical investigation into the phenomena to be expected when first or second sound passes through a phase boundary between solutions of helium-3 and helium-4 has been made by R. G. Arkhipov and I. M. Khalatnikov. They gave the equations for reflexion, refraction and conversion from one type of sound into the other for the cases when both or only one of the phases are superfluid. In another theoretical paper, by L. P. Gorkov and L. P. Pitaevsky, the scattering of light in helium-3–helium-4 solutions was calculated, and it was shown that whereas pure helium-4 should exhibit only four lines, the spectrum of the solutions should contain five. A theory of the momentum distribution of interacting particles in Fermi systems was proposed by A. B. Migdal.

Except for some theoretical considerations of the helium film by R. G. Arkhipov and a report on normal viscosity and the onset of friction given by the present author, the rest of the work on helium was concerned with rotation experiments. Both H. A. Hall as well as D. S. Zakadze and E. L. Andronikashvili described oscillation experiments in rotating liquid helium. An investigation into the existence of discontinuity surfaces in moving liquid helium, postulated by Ginsburg, has been made by G. A. Gamzemlidze, who concludes that the surface energy of such discontinuities cannot exceed 10^{-8} erg/cm.^{2}. A theoretical attempt to estimate the relaxation time of vortices in rotating helium has been made by Y. G. Mamaladze who, like the previous author, works in Tiflis. E. M. Lifshitz and L. P. Pitaevsky discussed the scatter of rotons on the vortex lines in rotating helium and have postulated that a strong interaction must exist between these two if the theory is to explain the experimental observations.

A good deal of the work on superconductivity dealt with the boundary conditions between the two states, using the Landau–Ginsburg theory as the guiding principle. The corrections due to relativistic magnetic interactions were taken into account by V. L. Ginsburg and L. V. Keldysh. The first author also presented a paper evaluating the spread of magnetic field around the equilibrium value in which supercooling and overheating might be expected. Closely connected with these considerations is an interesting theory of A. A. Abrikosov on the behaviour of superconductive alloys. The well-known fact of the gradual magnetic penetration over an interval of field values is considered as a basic property of the alloy rather than due to macroscopic inhomogeneities. Measurements of the surface tension between the superconductive and the normal state in very pure tin single crystals were reported by Y. V. Sharvin, who found that the observed values are of the same order of magnitude but somewhat smaller than the values predicted by the Landau–Ginsburg theory. The conditions for the possible occurrence of superconductivity in bulk samples of ferromagnetic materials were discussed by G. F. Zharkov. He suggests the use of flat ellipsoids of rotation with a large demagnetization factor as most suitable for the detection of superconductivity.

The method of thermal waves for determinations of heat conductivities and specific heats has been employed by N. V. Zavaritsky, who investigated tin, aluminium and zinc down to 0·15° K. Dependence of the thermal conduction on the shape and surface conditions of the specimens was observed as well as an exponential rise with temperature of the specific heat in all three metals. A survey of heat conductivity work on superconductors, carried out in Oxford, was given by the present author. B. G. Lazarev and A. I. Sudovtsov reported measurements of the volume change occurring in tin and lead when superconductivity is established in a magnetic field, and of the discontinuity of the expansion coefficient at this transition. They found good thermodynamical agreement with the data for the effect of pressure on the transition of these metals. The same authors, together with A. P. Smirnov, have observed superconductivity in thin beryllium films which had been deposited on a helium-cooled surface, the transition occurring at about 8° K. The depth of penetration in a very pure cadmium sample has been determined by N. S. Khaikin, using a high-frequency method. The measurements were carried down to about 0·2° K., where a value of 1·5 × 10^{-5} cm. (much smaller than the anomalously high value given by Hein and Steele) was found. Similar measurements on films of tin and mercury have been made by Miss L. A. Prozorova, who concludes that the dependence upon temperature of the depth of penetration is in good agreement with the Landau–Ginsburg theory. Further theoretical considerations based on these results were reported by B. M. Bolotovsky.

A general survey of the possibilities of Fermi surface investigations in metals was given by I. M. Lifshitz, and this was followed by a paper by A. B. Pippard on the Fermi surface in copper. Two separate sets of measurements on the influence of pressure on the de Haas–van Alphen effect were reported. One, by N. B. Brandt and V. A. Ventzel, dealt with a detailed investigation on bismuth; while in the work of B. I. Verkin, I. M. Dmitrenko and B. G. Lazarev, zinc and tin were studied as well. The amplitude of oscillations of susceptibility is decreased in all cases by the application of pressure. Another approach to the determination of the Fermi surface, through cyclotron resonance in metals, was discussed theoretically by M. Y. Azbel and E. A. Kaner, who have amplified their former work by calculating the surface impedance as a function of field and temperature over a wide range of fields. Experimental data of cyclotron resonance in tin were presented by P. A. Bezugly and A. A. Galkin, and a paper on cyclotron resonance in bismuth was given by R. G. Chambers. The theory of the anomalous skin effect in metals in the infra-red was discussed by R. N. Gurzhi.

The resistance minimum in gold has been investigated in some detail by N. E. Alekseevsky and Y. P. Gaidukov who, from magneto-resistance observations and measurements of the Hall effect and of the magnetic properties, have formed the opinion that at about 8 koersteds a change in the metal takes place which, however, requires further elucidation. The galvano-magnetic properties of bismuth, tin and aluminium have been studied by N. E. Alekseevsky, N. B. Brandt and T. I. Kostina. P. G. Strelkov and Miss I. N. Kalinkina have measured the specific heat of bismuth from 0·3° to 4·4° K. and found that it is composed of a cubic term and a very small linear term. The effect of isotopes on the heat conduction of dielectric crystals was discussed by R. Berman. O. V. Klyavin and A. V. Stepanov gave data for the mechanical properties of a number of metals at liquid-helium temperatures.

The last session of the conference dealt with magnetic phenomena. The energy spectrum of antiferromagnetics near the ground-state was discussed by M. I. Kaganov and V. M. Zukernik. A. H. Cooke reported on antiferromagnetism in some iridium compounds, and antiferromagnetism in anhydrous sulphates and carbonates of the transition metals was described by A. S. Borovik-Romanov, N. M. Kreines and Miss M. P. Orlova. The work of the latter authors has led I. Dzyaloshinsky to a theory of weak ferromagnetism in antiferromagnetic crystals which, based on Landau's ideas, explains the effect as due to relativistic spin-lattice and magnetic dipole interactions. The propagation of sound in ferromagnetics was considered by A. I. Akhiezer, B. G. Baryakhtar and S. B. Peletminsky, who postulate that it should be possible to excite magnetic waves by means of sound, and that under certain stated conditions this should be an easily noticed effect.

Two afternoons of the conference were devoted to visits to the cryogenic laboratories at the Institute for Physical Problems and at the University of Moscow. An interesting historical exhibit at the former was the first turbine used by Kapitza in the liquefaction of air. Among the various research installations on show, a helium-3 cryostat in Peshkov's laboratory was particularly impressive. In this ingenious device five litres (at N.T.P.) of pure helium-3, which forms the working substance, is circulated constantly. The gas condenses under pressure in helium-4 and is then expanded. Temperatures down to 0·3° K. can be obtained in this way and temperatures down to 0·5° K. can be maintained constant for indefinite periods. Peshkov and Miss Zinovieva showed us a photograph, taken in this apparatus, in which the separation of the two liquid phases of helium-3–helium-4 mixtures was clearly visible. At the University of Moscow we saw besides the research laboratories the cryogenic teaching course, where undergraduates were busy with their ten experiments involving liquid helium. One of them was just carrying out an adiabatic demagnetization.

The members of the conference came to know each other well on a whole day's boat trip arranged by Kapitza. The hospitality of the Academy and the friendly welcome of our Russian colleagues made our stay in Moscow a very pleasant one. The visitors expressed the hope that they will be able to induce their hosts soon to come to Britain for a return visit.

K. Mendelssohn

OBITUARIES

Prof. H. O. Wieland, For.Mem.R.S.

To-day the manufacture of steroids for medical purposes is an industry. Hundreds of scientists in academic and industrial life are engaged in research on these substances. All this activity properly began in Germany, and its modern phase really dates from the work of A. Windaus on cholesterol and other sterols, which began in 1903, and that of Heinrich Wieland, whose paper (with F. J. Weil) on the preparation of the 'stem' bile acid, cholanic acid, $C_{24}H_{40}O_2$, was published in 1912 (*Hoppe-Seyl. Z.*, 80, 287). Until 1949, fundamental discoveries, mainly about the occurrence in Nature and the chemical structures of bile acids, toad poisons and some sterols and alkaloids were published continually from Wieland's laboratories. These contributions have been reviewed, for example, by L. F. Fieser and M. Fieser ("Natural Products related to Phenanthrene". Reinhold, New York).

The award of a Nobel Prize in Chemistry to Wieland in 1927 and to Windaus in 1928 anticipated our full appreciation of the importance of their work and of the use which would be made of it.

When O. Rosenheim and H. King in 1932 (*Chem. and Indust.*, 51, 464) put forward their revolutionary chrysene structure for sterols and bile acids, Wieland and E. Dane (*Hoppe-Seyl. Z.*, 210, 268 ; 1932) were quick to see its advantages and almost at once proposed the formula now accepted. Wieland and his colleagues went on to show how this formula explained observations which they and the school of Windaus had collected for nearly thirty years.

At that time, the structures of the crystalline œstrogenic hormones which had been isolated independently by E. A. Doisy, C. D. Veler and S. Thayer (œstrone, 1929), G. F. Marrian (œstriol, 1930) and A. Butenandt (œstrone, 1929) from human pregnancy urine were still unknown ; a leap in our understanding followed the demonstrations that these hormones were related to cholesterol and the bile acids. The androgens, progesterone and the adrenal cortex hormones soon appeared in the same pattern. Antirachitic vitamins D were derived from ergosterol and, later, cholesterol. When Wieland and Dane (*Hoppe-Seyl. Z.*, 219, 240 ; 1933) and J. W. Cook and his associates, at the same time, converted a bile acid (deoxycholic) into a powerfully carcinogenic hydrocarbon (methylcholanthrene), the foundations of much present-day interest in steroids had been laid.

Many new sterols and bile acids have since been discovered, and we now know that the heart poisons of toads and in certain plants, some plant sapogenins and alkaloids, as well as triterpenes of diverse origin, can be regarded as steroids. We have become adept at converting common sterols and sapogenins like cholesterol, diosgenin and hecogenin into known hormones and D vitamins, as well as into other substances with many kinds of physiological activity. The principal steroids have been totally synthesized. Many chemical reactions of these substances can now be interpreted in terms of electronic theory. We have begun to understand how sterols are synthesized *in vivo* from simple substances like acetate and how sterols can give rise to bile acids and hormones. Studies of the metabolism of such hormones in the living body are far advanced. We grope towards comprehension of the significance of sterols themselves in living cells and of the means by which steroid hormones may affect cellular chemical reactions.

An immense amount of work remains to be done. No doubt fundamental changes in our appreciation of vital processes must follow or precede more complete understanding of the natural significance of steroids.

It is scarcely too much to say that without the work of Windaus, Wieland and their colleagues, no such achievements would have been possible, and no such exciting prospects would now lie before us. Prof. Windaus is still alive, but Prof. Wieland died recently at the age of ninety.

G. A. D. Haslewood

Prof. William Rowan

Dr. William Rowan, emeritus professor of zoology in the University of Alberta, died at Edmonton, Alberta, on June 30 at the age of sixty-five. Born in Basle, Switzerland, on July 29, 1891, he emigrated to Canada in 1908. For a time he worked on a ranch near Dorothy, Alberta, and, in later life, often spoke with some pride of his prowess as a cowboy. But while this outdoor life fostered a latent interest in biology, young Rowan's inquiring mind found this mode of development too slow and he soon went to Britain to complete his formal education. This was interrupted by the First World War. Rowan enlisted as a private in August 1914, and served with the London Scottish Regiment until 1916. He then returned to his studies and graduated in the following year from University College, London, with the B.Sc. degree. His artistic talents began to show at this time. A period of study at the Slade School of Art developed skills in drawing and sculpture. In future years his knowledge of animal life and a fine æsthetic sense combined to produce models and sketches of birds and mammals notable in particular for their flow of line. He studied music and became an accomplished pianist. So strong was his love of music that he thought seriously of turning to the concert platform. Throughout his life he was never quite certain that he had made the right choice in following the path of science.

After the War, Rowan returned to Canada to lecture in zoology for a year at the University of Manitoba. In 1920 he went to the University of Alberta at Edmonton, where in the following year, with the rank of associate professor, he founded the Department of Zoology. He remained as head of this Department until his retirement in 1956. He was a popular and stimulating lecturer, fond of using startling statements to shake students from their mental lethargy.

Of the various branches of zoology, Rowan had always shown a preference for ornithology and now, established in a university community, he proceeded to investigate some of the problems which had intrigued him for years. One of these was the migration of birds. He postulated that there is an inherent migratory habit in some species of birds which is impelled by a hormone the production of which is controlled by the environmental factor of changing day-length. Working at times under great difficulties, he kept canaries and juncoes in cages in his own garden and produced the first experimental evidence that fluctuations in day-length cause a cyclical development and regression of the gonads of birds. This was the first step in proving the hypothesis that photoperiodism is a controlling factor in the phenomenon of avian migration. In further experiments he attempted to make juncoes sedentary during the normal migratory period and to reverse the usual direction of migration in others. The results of this work were presented in a thesis for the D.Sc. degree of the University of London in 1929. In that year, also, Rowan was elected a Fellow of the Zoological Society of London.

Results of the experiments with juncoes were not conclusive. This, Rowan felt, was largely due to the small size of the bird, with consequent difficulty in recognizing and recapturing the experimental birds. He therefore determined to repeat the experiments using crows as subjects. The publicity attendant upon capture, treatment, release and recapture of these birds put his work and his name upon the tongues of laymen throughout North America and undoubtedly assisted greatly in popularizing science. His book, "The Riddle of Migration", published in 1931, included the results of this work and brought him international recognition. It also marked the beginning of a decline of interest in the problem of migration. His scientific efforts were henceforth largely directed toward a study of the cyclical fluctuation in numbers of certain species of North American birds and mammals, a study which he felt was essential to a complete understanding of the problems of conservation on the continent. In 1946 he was awarded the Flavelle Medal of the Royal Society of Canada in recognition of his investigations. He was working on various aspects of animal cycles at the time of his death.

Always a firm believer in an oligarchy of the intelligentsia, Rowan looked upon the events following the Second World War as conclusive evidence of the depravity of democracy. He was convinced that mankind is heading towards total self-destruction and that it can be saved only by placing itself under the guidance of an intellectual few; after the development and use of the atom bomb his prognostications became even more gloomy.

Rowan's influence in the field of experimental ornithology will long be felt. The world-wide circle of friends with whom he discussed favourite subjects over coffee and cigarettes will feel not only a sense of great personal loss but also sincere regret at the passing of a large heart and a fine mind.

W. Ray Salt

Dr. Gerald Roche Lynch, O.B.E.

The death of Roche Lynch at the age of sixty-eight on July 3, at his home in Slough three years after retirement, ended a long period of distinguished service to medical science. It also erased the name of the last of a group of remarkable men, including Pepper, Luff, Spilsbury and Willcox, who for thirty years in the first half of this century had been the mainstay of the Home Office in scientific crime investigation in England and Wales.

Roche Lynch, whose father was a Kensington medical practitioner, was educated at St. Paul's School and entered St. Mary's Hospital, London, in 1905, gaining an entrance scholarship in science and, a year later, the prize in chemistry. This was undoubtedly the turning point in his career, for while still studying medicine he also trained in chemistry under H. E. Armstrong at the City and Guilds Institute and demonstrated in the subject at his own medical school. The latter appointment brought him under the influence of William Willcox, who then lectured in chemistry, and together they were drawn into the practice of Pepper and Luff, no small part of which was medico-legal. Qualifying in medicine in 1913, Roche Lynch served in the Royal Navy until 1919, when he was appointed O.B.E. Returning to St. Mary's as senior demonstrator in pathological chemistry, he was made head of the Department in 1926 and continued so until he retired in 1954. Willcox had him appointed junior to him as Home Office analyst in 1924 and he succeeded to the senior appointment four years later.

Roche Lynch was undoubtedly happiest at work in his somewhat untidy-looking laboratory at St. Mary's where, surrounded by the stalagmitic accumulation of what seems years of specimens, he never failed to find room for another 'most interesting case', to display a penetrating grasp of its nature and to keep orderly hand-written notes which were good enough to survive defending counsel's scrutiny on many an occasion. It was from this laboratory that he made literally thousands of appearances in coroners' and assize courts between 1924 and 1954 to give his findings in evidence. In this he was superb, for he had mastered the art of extraction without loss of accuracy, and, though precise, he gave sufficient hint of thoroughness of method and of painstaking laboratory care to deter defending counsel from pressing him far. He was a fine analytical chemist of the older school whose work in cases like that of Duff and Sydney, Violette Kaye, Vera Page and Sidney Fox was so sound that it acquired a remarkable reputation and gained him the respect of both the Bench and the Bar. Affection he did not encourage, and the Savage Club was virtually his sole excursion into social life.

He examined for Branch *E* for the fellowship of the Royal Institute of Chemistry—of which he was president during 1946–49, and he also examined for the London M.B. and the D.P.H. He became president of what is now the Society for Analytical Chemistry in 1936–37, of the Medico-Legal Society in 1939–41, and master of the Society of Apothecaries in 1950–1, filling these distinguished posts with a strong practical authority and with disarming humility. He was both liked and respected, and his long era of service to medicine and science, to the field of chemistry—in which he wrote many papers—and to university life in London will mark him as one of the distinguished figures of twentieth century medical science.

KEITH SIMPSON

NEWS and VIEWS

Civil Engineering in Trinity College, Dublin : Prof. John Purser

PROF. JOHN PURSER, a member of a family whose name has been synonymous with that of Trinity College for many years, will retire from the chair of civil engineering in the University of Dublin on September 21. Prof. Purser graduated in engineering in Dublin in 1907, and decided to make his career as a teacher. He joined the Navy in the First World War, serving first in motor torpedo boats and later with a team working on paravanes. After the War he taught in the City and Guilds College in London, and later in the University of Birmingham. His research interests were the deterioration of structures in sea water, and the flow of rivers. He returned to Dublin in 1933, and devoted himself to teaching and to guiding the growth of the School of Engineering. After the Second World War, the premises of the School were reconstructed and enlarged, and a fourth year has recently been added to the course. The School is for civil engineering only, and Prof. Purser has had the satisfaction of seeing his graduates sought for by works departments all over the world. He has given freely of his time to the general affairs of the College, to the Institution of Civil Engineers in Ireland and to the Commission of Irish Lights, and all these bodies look forward to continuing to draw on his experience and advice.

Prof. W. Wright

DR. W. WRIGHT, who is succeeding Prof. John Purser, has been senior lecturer and head of the Civil Engineering Department in the University of Southampton since 1954. His main fields of interest have been structural engineering and hydraulics. In structures he has been particularly concerned with applications of the relaxation method. In hydraulics he will be remembered at Southampton for the design and commissioning of a large tidal model of the Solent and Southampton Water. Because of the need for two separate tidal generators at the two entrances to the Solent, this model proved exceptionally difficult to bring under control, so that the complex local tides could be correctly reproduced. Dr. Wright was successful in overcoming these difficulties in the short time available to provide the necessary information for a proposed dredging project.

Nuclear Physics at Oxford : Prof. D. H. Wilkinson, F.R.S.

DR. D. H. WILKINSON has been appointed to the professorship of nuclear physics (established with the late Sir Francis Simon's support after he had succeeded Lord Cherwell as Dr. Lee's professor of experimental philosophy) at the Clarendon Laboratory, Oxford. Dr. Wilkinson graduated at Cambridge in 1943 and became a Fellow of Jesus College in 1945. For a short time he worked with the first heavy-water reactor at Chalk River in Canada ; however, in the course of this or his previous work he had become exposed to more radiation than was good for him, and back in Cambridge after the War he accepted, for a time, a medical injunction to keep away from penetrating radiations and hence from nuclear physics. It was during that time that he started to work on how homing birds find their way, and he made some valuable contributions by exploding some untenable hypotheses and by inventing a simple radioactive clock for measuring the time a bird spends on the wing (*Nature*, 161, 997 ; 1948, and 165, 188 ; 1950). Fortunately, his health fully recovered and soon he was back in nuclear physics. His numerous contributions range from the development of ingenious new measuring techniques to the skilful exploitation of new theoretical concepts (such as isotopic spin); he was elected a Fellow of the Royal Society in 1956. More recently, after a year's stay in the United States, he turned to the exploration of the strange particles which abound near particle accelerators of the highest energy. To his new appointment he brings a lively and versatile mind, a wide knowledge of physics, a gift for clear and vivid presentation and a subtle sense of humour.

Chemical Engineering at Birmingham : Prof. S. R. M. Ellis

DR. S. R. M. ELLIS, who has been appointed to the second chair in the Chemical Engineering Department of the University of Birmingham, had a wide industrial experience before becoming interested in university teaching. He is forty-four years of age and was born in New Zealand and studied in Auckland University, where he graduated and obtained the degree of master of science. He had extensive experience in the fuel industry in New Zealand before coming to Britain in 1937. Initially he was connected with the Low-Temperature Carbonization Oil Refinery at Bolsover, as chemical engineer on both the operating and design sides. He then became a senior chemical engineer to a chemical plant manufacturer, designing and fabricating complete chemical plants for the chemical industry. He joined the Chemical Engineering Department at the University of Birmingham in 1947, was appointed senior lecturer in 1949 and reader in 1955. He has been closely associated with the Institution of Chemical Engineers, Midlands Branch, as honorary secretary and has served on a number of educational committees. He has played a very active part in the teaching work of the University and in research activities, centred largely on distillation work, including vapour-liquid equilibria over a range of pressures and determinations and method of operation of various forms of distillation plate columns.

Grants for Learned Journals : Dr. F. V. Morley

THE joint committee of the Royal Society and the Nuffield Foundation which administers grants made available by that Foundation to assist learned scientific journals has appointed Dr. F. V. Morley as liaison officer. The committee, presided over by Sir Edward Salisbury, has already made a number of grants to aid journals which are concerned in primary subjects of research. Dr. Morley's father, Frank Morley, was a Cambridge mathematician who (following a distinguished pattern which had been set before his time by J. J. Sylvester) became head of the mathematical department of the Johns Hopkins University, and from an early age the son was familiar with and interested in the problems attendant on the production and distribution of the *American Journal of Mathematics*. Writing, publishing, journalism, and respect for all branches of research were much in the blood of the Morley family of Baltimore. The eldest son, Christopher Morley, was a publisher before he became well known as a writer; the second son, Felix, became editor of *The Washington Post*, and after that president of Haverford College; the third son is the present appointee of Sir Edward Salisbury's committee.

All three of the Morley brothers were Rhodes Scholars at New College, Oxford. F. V. Morley took his D.Phil. at Oxford in mathematics, but instead of returning to teach in the United States he married and settled in England. He was on the staff of *The Times*, but left to become London manager for the Century Company of New York, and afterwards, in 1929, was one of the founding directors of Faber and Faber. He shared a room with Mr. T. S. Eliot and, as he says, shared in the headaches of publishing *The Criterion*. In 1939 he was invited to New York to become a director, and afterwards vice-president, of Harcourt, Brace and Co. In 1947 Mr. Morley (for outside academic circles he has never used his academic title) returned to London. In 1949 he became a director of Eyre and Spottiswoode (Publishers), Ltd., and of E. and F. N. Spon, Ltd. Dr. Morley retired from publishing a year ago, but it will be seen that he has had a wide and varied experience which the committee hopes may prove of practical value to those concerned with the production and distribution of learned and specialized journals. Perhaps the best possible assistance that can be rendered to the journals resides in increase of circulation, if that can be managed without any interference with editorial policy or any lowering of standards. Every promising effort to promote subscriptions for British journals, especially overseas, will certainly be welcomed. Inquiries may be addressed to Dr. F. V. Morley, Nuffield Lodge, Regent's Park, London, N.W.1.

Brazilian Society for the Progress of Science

THE annual meeting of the Brazilian Society for the Progress of Science was held this year during July 8–13, for the first time in Rio de Janeiro. The president for this ninth meeting was Prof. Fritz Feigl, director of the Microchemical Laboratory of the Brazilian Department of Mineral Production. The inaugural session, which was attended by the Minister of Education, opened with the reading of a goodwill telegram to the Society from the British Association. During the following days, some 294 papers (contributed by 362 scientists) were presented in the various sections, and there were also nineteen sectional discussions. About two-thirds of the papers were presented in the biological or medical sciences. Of the remaining subjects, education, chemistry and physics were well represented. Evening lectures included talks by Prof. Walter Cruz on "The Social Importance of Science", by Sr. Oscar Niemeyer on the project for the construction of the new capital of Brazil, and by Mr. F. M. Beatty, the acting representative of the British Council in Brazil, on "The British Association". There were eighteen symposia and discussion meetings, including a discussion on the functions of Brazilian scientific institutions. The next annual meeting is planned to take place in São Paulo in July 1958.

Association of Island Marine Laboratories

THE remarkable growth of interest in marine biology in the tropical western Atlantic was made apparent by a conference held during April 1957 at the marine laboratory of the University of Puerto Rico at Maguey, with financial support from the U.S. Office of Naval Research. The conference was attended by representatives from the Marine Biological Station and the Government Aquarium at Bermuda, the Lerner Marine Laboratory at

Bimini, the Bellairs Institute of McGill University in Barbados, the Caraibisch Marien-Biologisch Institut in Curaçao, the University College of the West Indies in Jamaica and the Universities of Oriente, Villaneuva and Nacional and the Oficina Hidrográfica in Cuba. Several of these institutes are less than three years old, and this was the first occasion on which most of the participants had met each other. The conference was restricted to laboratories established on islands in the area of reef-building corals of the tropical western Atlantic, which extends from the eastern islands of the Caribbean to Bermuda. Throughout this great sea area the marine flora and fauna and the hydrographic conditions are remarkably uniform, and in consequence the participants found a considerable field of common interest in the problems with which they are concerned.

The conference was felt to be of such value by the participants that a permanent Association of Island Marine Laboratories was established to keep its members in touch with each other, to exchange information and to co-operate in research programmes that affect the whole area. The Association hopes also to arrange visits and exchange of experts in special fields of study. A publication is to be issued shortly, giving information on the facilities for research offered by the member institutes, and consideration is being given to the founding of a journal to publish papers on the biology of the area. It is hoped to hold the next conference of the Association in Bermuda in 1958. Prof. D. M. Steven, of the University College of the West Indies, was elected its first president, and Dr. Juan Rivero, director of the Marine Laboratory of the University of Puerto Rico, its secretary.

English Translations of Russian Medical and Biological Journals

The Pergamon Institute, London (4–5 Fitzroy Square, W.1) and New York, is a non-profit-making foundation which has been formed for the purpose of making available to English-speaking scientists, medical men and engineers, the results of research in the U.S.S.R. It has the support of an honorary advisory council containing the names of distinguished research workers from many different countries. The formation of the Institute was stimulated by the recent report of the United Kingdom Government Advisory Council on Scientific Policy (*Nature*, 178, 1255 ; 1956), which suggested that only about 2 per cent of British working scientists can read Russian compared with 80–90 per cent who read French and 60 per cent who read German. As part of its activities, the Institute has just started the complete translation of a number of Russian medical and biological journals, the first to appear being the *Journal of Microbiology, Epidemiology* and *Immunobiology* (from Vol. 28, issued in monthly parts ; annual subscription £18), *Biophysics* (from Vol. 2, eight issues per annum, £10 14*s*.), *Problems of Virology* (Vol. 2, bimonthly, £7 p.a.) and *Problems of Hematology and Blood Transfusion* (Vol. 2, monthly, £7 p.a.). The *Physiological Journal of the U.S.S.R.* (Sechenov) and *Problems of Oncology* will also be translated.

Publication is supported financially by the National Institutes of Health, United States Department of Health, Education and Welfare. It has been possible to arrange for early copies of the journals and the original illustrations to be made available from the U.S.S.R. with the result that publication has been astonishingly prompt : some of the original papers bear dates in late 1956. The translations read easily and the printing and production are of high quality. The bibliographies of the papers are set out very clearly and they show that Russian workers are making a lot of use of journals from English-speaking countries. These translations will help to make the transmission of information a more mutual one. The continued success of the scheme will depend on a sufficient supply of translators to carry on the work, and the Institute invites offers from suitably qualified people who would be willing to help. Translations of individual papers in Russian, and also of some scientific journals, are already available from Consultants Bureau, Inc., 227 West 17th Street, New York, but the Pergamon Institute has the advantage that it is a non-profit-making body.

Biochemistry of Sulphur

A colloquium on the biochemistry of sulphur was held in May 1956 in the biological station at Roscoff, at which thirty-four invited specialists from seven countries took part. The papers which were given and the discussions which followed have now been published (Colloque sur la Biochimie du Soufre, Roscoff, 14–18 Mai 1956. Pp. 244. Paris : Editions du Centre National de la Recherche Scientifique 1956). In his introduction, Prof. C. Fromageot points out that in living matter sulphur occurs in a variety of forms—as thiols, disulphides, thioethers and heterocyclic compounds, whereas phosphorus occurs only as orthophosphates or their anhydrides. New techniques, particularly those of chromatography and the use of radioactive sulphur, have led in the past few years to a rapid increase in knowledge of the biochemical transformations and catalytic actions of substances containing sulphur. The main emphasis at the meeting was on sulphur compounds in the higher animals, though the first two sessions contained papers on the sulphur metabolism of micro-organisms. In the third session Prof. P. Handler dealt with the last stages in the oxidation of cysteine, and described experiments leading to the unexpected discovery that hypoxanthine may act in conjunction with lipoic acid as a reducible carrier in the oxidation of sulphite in animal tissues. Sulphatases were discussed by K. S. Dodgson and by B. Spencer and the metabolism of steroid sulphates by A. B. Roy. Administration of inorganic sulphate containing radioactive sulphur to some of the higher animals showed that the sulphur is incorporated into organic compounds in a manner which differs according to the species of animals used (P. B. Pearson). Ruminants incorporated inorganic sulphur at a rate sufficient to be of nutritional importance, probably owing primarily to activities of micro-organisms in the alimentary tract. This paper produced a lively discussion which included the plea that the term 'detoxication', with its teleological implications, should be dropped from the biochemical vocabulary. Among other topics included in the Colloquium were the metabolism of sulphur in relation to vitamins of the B group, the metabolism of cystamine, and enzymic reactions involving thioesters. In the review copy of this book, pages 113–128 were omitted and duplicates of other pages bound in their place.

Indonesian Museums

Mr. J. Irwin has recently summarized the conclusions drawn during a six-month Unesco mission to Indonesia in an article in the July issue of the *Museums Journal*. After a rapid survey of the present position, he was convinced that the most urgent problem was the lack of trained personnel. It was thus recommended that potential candidates should first receive a basic training course in Indonesia—probably a year at the Djakarta Museum—and then be awarded a travelling fellowship in Europe or America to specialize in some particular aspect relevant to Indonesia's specific needs. Mr. Irwin further considered that if museum development is to receive substantial support from the authorities it must play a positive part in the major national aim of fostering a consciousness of the Indonesian motto, "Unity in Diversity". To this end about thirty acres of land near the capital has been purchased for a national museum, and around the periphery it is planned to erect spectacular examples of traditional domestic architecture brought from the main cultural regions of Indonesia. Each of these houses is to be set in its own botanical setting and furnished in its own traditional way. This part of the scheme illustrates the diversity of Indonesian culture, while the unity would be shown in a modern functional building sited in the centre of the park, illustrating the links in Indonesia's cultural development. The whole project has been designed to be completed in ten years, and the acquisition of the land for 1,250,000 rupees is an indication that the authorities are keen to accept the recommendations of the Unesco report.

Mathematics in Industry

The alarming shortage of competent mathematical teachers in British schools is already responsible for a shortage of good young mathematicians available for industry. As the language of science, mathematics is a major pillar of any technological economy, and the Mathematical Conference for Schoolteachers and Industrialists held at Trinity College, Oxford, during April 8–18 was based on this brute fact. The "Abbreviated Proceedings" (pp. 112. London: *Technology*, Times Publishing Co., Ltd., 1957. 2*s*. 6*d*.) therefore contains matter of national interest and importance, meriting the attention of parents, administrators and politicians. Industrialists expounded their mathematical needs and the wide variety of mathematical applications; research scientists helped to bridge the gap between pure mathematics and technology; teachers considered how content and exposition of a school curriculum might be modified to provide an adequate preparation for industrial mathematicians without thereby losing sight of the concept of mathematics as a part of general culture and education. Teachers present at the conference spoke warmly of the great stimulus and encouragement received, and hoped that further meetings may be arranged.

Nature Conservancy Awards for 1957

17

The Nature Conservancy announces the following awards of research studentships for postgraduate training in ecology, tenable for periods up to three years at the universities shown: *Botany*, Miss B. C. Barrett (Durham–Newcastle), Miss D. C. Munroe (London), Miss C. M. D. MacDonald (Oxford), E. I. Newman (Cambridge), G. A. M. Scott (University College of North Wales, Bangor); *Zoology*, J. M. Cherrett (Durham), L. M. Cook (Oxford), I. E. Efford (Oxford), J. E. C. Flux (Aberdeen), J. F. Peake (London).

Announcements

Dr. Nicholas Kurti, of the Clarendon Laboratory, Oxford, is the first recipient of the Fritz London Award, which will be given biennially for distinguished research in low-temperature physics and chemistry as a memorial to the late Fritz London, of Duke University, North Carolina. Arthur D. Little, Inc., industrial research consultants of Cambridge, Mass., is sponsoring the tribute this year and will sponsor the award again in 1959.

The next meeting of the American Association for the Advancement of Science will be held during December 26–30 in Indianapolis. Further information can be obtained from the A.A.A.S., 1515 Massachusetts Avenue, N.W., Washington 5, D.C.

The Plastics and Polymer Group of the Society of Chemical Industry is to hold a symposium in London during April 15–17, 1958, on "The Physical Properties of Polymers". The symposium will be devoted to recent advances in the fundamental investigation of mechanical and electrical processes in polymers, and to the physical testing of plastics, rubbers and fibres, with particular reference to dynamic and relaxation methods. All inquiries and offers of contributions to the symposium should be made to the honorary recorder, Mr. K. H. C. Bessant, c/o The Distillers Co., Ltd., Great Burgh, Epsom, Surrey.

A course of lectures on "Observations of Dislocations in Metals and Inorganic Crystals" will be given in the H. H. Wills Physical Laboratory, University of Bristol, during March 24–29, 1958. The lecturers will be Prof. F. C. Frank, Dr. J. W. Mitchell, Dr. J. F. Nye, Dr. N. Thompson and other research workers. Those attending can be accommodated in Wills Hall, one of the halls of residence of the University. Further information can be obtained from the Director, Department of Adult Education, University of Bristol.

An International Conference on High Polymers will be held at the University of Nottingham during July 21–24, 1958. Proceedings will be divided between two sections meeting simultaneously, the main subjects to be discussed being: *A*, reaction mechanisms and kinetics, heterogeneous polymerization (including trapped or inactive radicals), production of graft and block co-polymers; *B*, physical, thermodynamic and mechanical properties. Those wishing to present a paper should submit an abstract of 200–300 words in English, French or German, not later than December 15, 1957, to the International High Polymer Conference, The University, Manchester 13. The organizing committee will make up its programme by selection from these abstracts, and will invite the authors to prepare their completed papers not later than March 1, 1958. The full proceedings of the Conference, including the discussion, will be published in the *Journal of Polymer Science*.

MATERIALS FOR NUCLEAR ENGINEERING

THE summer meeting of the Physical Society took the form of a two-day conference on "Materials for Nuclear Engineering". It was organized with the help of Associated Electrical Industries Ltd., and was held at the Associated Electrical Industries Research Laboratory, Aldermaston, during July 11–12.

Dr. T. E. Allibone (director of the Research Laboratory, Associated Electrical Industries Ltd.) opened the conference with a general review of the problems encountered in finding suitable materials for nuclear engineering and their importance in the future development of nuclear energy. He considered it very appropriate for the Physical Society to arrange a conference to discuss the physical properties of materials rather than their technology, for the technological questions would no doubt be answered when the underlying physics was better understood.

The papers delivered at the Conference could be classified into four groups: irradiation effects, physical properties of particular metals, liquid metals and the structure of materials.

Irradiation effects were discussed in four of the papers. Dr. A. H. Cottrell (Atomic Energy Research Establishment, Harwell) considered the effect of irradiation on creep. The importance of this problem was due to the fact that materials, although not subject to movement, had to withstand stresses at fairly high temperatures. The main effects of irradiation were the production of vacancies and interstitials, structure changes, radiation hardening, and the generation of internal stresses. Since the movement of vacancies was the vital factor affecting the creep-rate, it might be expected that if the coefficient of self-diffusion was high, poor creep properties would result, and he suggested that it was a good idea to use materials for which the diffusion coefficient is less than 10^{-15} cm.^{2}/sec. Cottrell calculated that the effect of irradiation on the diffusion coefficient kept its value less than the critical 10^{-15}, and thus there was no significant change in creep properties due to this cause, as was in fact found in the early experiments. Structure changes could be caused by irradiation; for example in the uranium/molybdenum system, irradiation changes the structure from α-uranium + ε to γ-uranium in the quenched alloy at 400° C. Radiation hardening helped creep properties, but usually this occurs at temperatures lower than those where creep is important. Internal stresses can cause creep when they arise in a non-Newtonian body, and may be caused by thermal gradients, growth strains, thermal cycling strains and swelling. Growth strains are caused by a non-cubic crystal changing its shape, and in α-uranium this change is an expansion in two directions plus contraction in a third; the increased creep-rate has been observed experimentally.

Irradiation effects in insulating crystals were considered by Prof. R. W. Ditchburn (University of Reading). In order to understand the effects of pile neutrons it is desirable to study the displacement of single atoms to form vacancy interstitial pairs. This can also be done by using electrons of controlled energy (about 0·5 MeV.), but local heating must be reduced in order to avoid partial annealing. The damage produced is studied by measuring the change of some physical property, and optical absorption is a particularly powerful method of investigation for it gives the energy-levels and the relative numbers of displaced atoms. For diamond, it is possible to investigate the displacement of single atoms. Experiments showed that heating at 450° C. causes some annealing; at 600° C. it causes the formation of pairs of defects and at 900° C., after prolonged heating, agglomerations of defects occur. Another valuable technique for the understanding of irradiation damage is the study of the polarization of irradiation-induced fluorescence, and by this means it is possible to deduce the orientations of defect systems.

Dr. G. B. Greenough (U.K. Atomic Energy Authority, Windscale) discussed irradiation effects in graphite. When it is exposed to neutrons with energies greater than 100 eV. at temperatures below 150° C., vacancies and interstitials are created, which cause changes in the physical properties. Thus the thermal and electrical conductivities decrease by factors of thirty and three respectively, and Young's modulus and the breaking strength increase by a factor of two. Changes in the external dimensions of a block of graphite also occur due to the fact that the c and a interatomic spacings increase and decrease respectively. Annealing the graphite restores its physical properties, but temperatures in excess of 1500° C. are required for full restoration. The annealing process, which causes the return of interstitials to vacant lattice sites, is accompanied by a high energy release. Dr. Greenough stressed the fact that experimental work is somewhat difficult because the properties of unirradiated graphite depend on its method of manufacture, and thus many samples must be investigated.

Dr. R. S. Barnes (Atomic Energy Research Establishment, Harwell) and Dr. A. T. Churchman (Associated Electrical Industries Ltd.) considered the structural effects in solids of nuclear-induced gases. These, which are generally of the rare-gas type, result from nuclear reactions caused by neutron irradiation, and can cause drastic structural changes in the material which is used. For example, boron and boron carbide, both of which are brittle, fragment upon irradiation with thermal neutrons, there being a helium-producing reaction in boron. It is believed that in each of these materials, the included gas diffuses to flaws, so creating a gas pressure which causes crack propagation resulting in fragmentation. The behaviour of deformable materials containing gas is quite different from that of brittle materials. From experiments on irradiation of beryllium by 40 MeV. α-particles producing helium, and of uranium by thermal neutrons, when the rare gases xenon and krypton are among the gaseous products, it was concluded that at low temperatures large quantities of the inert gases can exist in materials without causing an appreciable increase in volume. Heating permits the precipitation of the gas into bubbles if the material is ductile, or it cracks if it is brittle. The size and number of bubbles or cracks are determined by the presence of nuclei, the diffusion coefficient and the solubility of the gas. It was found that the increase in volume caused by bubble formation depended upon the distribution of the gas, and that if the bubbles were small and numerous the gas was contained at a very high pressure and the resulting increase in volume was small. But if the same amount of gas was distributed in a few large bubbles, a large volume increase resulted. Such increases in volume could be troublesome in a reactor since, for example, it may cause splitting of the fuel can, allowing corrosion, or impeding the flow of coolant.

The physical properties of particular metals were dealt with in two papers. Mr. G. C. Ellis (Atomic Weapons Research Establishment, Aldermaston) delivered a paper on beryllium and in particular discussed the problem of its brittleness. This metal has attractive nuclear and high-temperature properties, but the main difficulty in its use is its relatively low ductility. Mr. Ellis reviewed the metallurgy of beryllium and considered the methods of producing the ductile metal by controlling the grain orientation. He considered that a considerable improvement might be obtained by removing interstitial solute impurities. However, the problem of purification, especially on a large scale, was likely to prove very difficult, but he suggested that there was sufficient justification to make the necessary effort.

The physical properties and alloying behaviour of plutonium were discussed by Dr. M. B. Waldron (Atomic Energy Research Establishment, Harwell). He stressed that the two most distinctive features of plutonium were its radioactive toxicity, which with its inherent difficulties slowed up the progress of research with the metal, and its allotropic behaviour, for six different forms of the metal have been identified. The relative stabilities of the various forms are of particular interest. Although certain similarities existed between plutonium and uranium phase diagrams, to assume direct analogies between the two was very dangerous. Dr. Waldron produced data on the specific heat at low temperatures and on dilatometric studies. Of particular interest was the negative coefficient of thermal expansion of the face-centred cubic δ-phase. This is unique for a metal with an isotropic crystal structure and emphasized the abnormal behaviour of the plutonium atom. In the discussion on the paper, Dr. E. Dempsey (Atomic Weapons Research Establishment, Aldermaston) contributed data on the Young's modulus and oxidation properties of the metal.

During the course of the conference it was evident that the subject of liquid metals was very important, and three papers were read on various aspects of it. Dr. B. R. T. Frost (Atomic Energy Research Establishment, Harwell) delivered a paper on the wetting of solids by liquid metals. He outlined the role taken by liquid metals in reactor technology, and stressed that in all the fields of use, wetting problems arise. This usually means that it is necessary to know the condition at the interface between the liquid metal and the solid metal under consideration. Definitions of wetting are usually given in terms of the contact angle θ, and for metallurgical application it is convenient to use $\theta = 90°$ as the dividing line between 'wetting' and 'non-wetting'. It depends on the balance of solid and liquid surface tensions, or in other words on the degree to which the solid and liquid interact. For a quantitative understanding of the process of wetting it is necessary to measure the surface tensions of the solid and liquid, and also their interfacial tension, and Dr. Frost gave an account of the various methods of measuring these quantities. He discussed the inducement of wetting by the addition of elements (wetting agents) to the liquid metal, and mentioned the part that fluxes can play. As particular examples of the problems encountered, he mentioned the wetting of particles in slurries where the liquid metal acts as a fuel carrier, the wetting of surfaces in an electromagnetic pump, wetting during brazing, and also the problem of corrosion.

A special type of corrosion is mass transfer, which was discussed in a paper by Dr. A. K. Covington, Dr. G. A. Geach and Dr. A. A. Woolf (Associated Electrical Industries Ltd.). It is a process whereby a liquid or vapour takes up a solid at one point by chemical reaction or solution, transfers it by mass flow to a point where conditions differ and there allows it to be re-deposited. This deposition may be a consequence of change in temperature or it may be due to chemical reaction with another material. Mass transfer can be one of two types. Thermal gradient mass transfer arises when a liquid metal is confined in a solid metal system subjected to a temperature gradient. The difference in solubility of the container material in the liquid metal at different temperatures results in solution in the hotter portions and precipitation in the colder portions, with subsequent rapid blockage of the system. Ways of reducing such transfer were discussed with particular reference to the formation of inhibiting layers of zirconium nitride on steels. Isothermal mass transfer can occur when two dissimilar metals are placed in a liquid metal. Some affinity between a metal soluble in the liquid metal and one less soluble can lead to the formation of a layer of an intermetallic compound or solid solution on the less soluble metal. For example, aluminium has been observed to transfer on to the surface of pure iron, causing the formation of Fe_2Al_5. As in the inhibition of thermal mass transfer by zirconium nitride, the presence of free nitrogen in the iron may prevent transfer of aluminium probably by the formation of an aluminium nitride film.

The third paper connected with liquid metals was that by Mr. J. S. Hilditch (British Thomson-Houston, Rugby) on the electromagnetic pumping of liquid metals. The great advantage of the electromagnetic pump over its mechanical counterpart is that it allows liquid metals to be circulated at high temperatures without glands, seals or moving parts. Principles upon which such pumps operated were described, and the performance figures given for some d.c. and a.c. conduction pumps. Alternating current induction pumps of the spiral, flat, annular and re-entrant types were also explained. The future of electromagnetic pumps appeared to be in their large-scale application to power reactors, and for bismuth the choice lay between the d.c. conduction pump with homopolar generator and the low-frequency a.c. conduction pump with separate transformer, or possibly the rotating-magnet induction pump. However, for sodium and sodium potassium alloys, where the resistivity was lower, the flat or re-entrant annular type of linear induction pump was favoured.

The structure of materials was dealt with in two papers. Dr. J. Friedel (Ecoles des Mines, Paris) discussed possible causes for allotropic transformations in the heavier elements. He first compared the behaviour of these elements with those of the first period transitional metals. In the period commencing with francium and extending to americium, a big drop in the melting point occurred at uranium, while very complicated crystal structures existed for those elements showing allotropy. This was due to the presence of homopolar unsymmetrical binding caused by the filling of the *f*-shells as well as the *d*- and *s*-shells. In uranium, this operation of both *d*- and *f*-states gave rise to an unsymmetrical crystal structure, while on heating the *d*-bonds were broken, causing anomalies in the linear expansion, abnormally small electrical resistivity and, at higher temperatures, a change in crystal structure to β- and γ-uranium. Americium existed in only one form with a peculiar double hexagonal close-packed crystal structure, indicating the beginning of a rare-earth behaviour with the electrons not forming bonds but existing in independent shells. Thus Dr. Friedel considered that the elements of low atomic number in the range had a structure similar to the transition metals, with a mixture of *d*- and *f*-orbitals giving rise to directional homopolar bonding, while for plutonium and americium the structures were more analagous to the rare earths, with the electrons in the *f*-shells predominating over those in the *d*-shells.

Some aspects of structure and solid solution were considered by Dr. G. K. Williamson (Atomic Energy Research Establishment, Harwell). The alloying behaviour of uranium was discussed with the view of determining its behaviour empirically. There was negligible solubility in the complex α- and β-structures and in the body-centred cubic γ-structure; it was restricted to the transition elements (Group IV*A* onwards). The Hume-Rothery size factor rule was obeyed for the elements of the first two long periods, but this is not so for elements of the third long period, and the reason for this is not yet understood. Uranium forms a large number of compounds, but it seems remarkable that, apart from those with a special size factor, no compounds are formed with elements of lower electronegativity. The compounds formed cannot be accounted for on the basis of electron compounds, for the effective valency of uranium is uncertain.

The conference was concluded with a talk by Sir John Cockcroft (Atomic Energy Research Establishment, Harwell) on the place of metallurgical development in the atomic programme. Future reactors would require fuel elements operating at higher temperatures, with higher heat ratings and burn-ups than those at present in use. Ratings could be increased in two ways. The surface area to volume ratio of the fuel element could be increased by using clusters of thin rods or plate fuel elements, but these were limited by fabrication problems or by the increase in the ratio of canning material to fuel. Again, the fuel element temperature could be increased, but this causes swelling in metallic uranium at 550–600° C. This difficulty could be overcome by using a 14 per cent molybdenum alloy, but such a degree of alloying is too high for thermal reactors, although it may be applicable for use in fast reactors. At temperatures above 600° C., it is necessary to use ceramic materials, uranium oxide or uranium carbide, as fuel, but these have their difficulties. With such high operating temperatures, beryllium cans are required and experiments have been carried out to test their ability to withstand such temperatures. By a combination of methods, it is hoped to increase the rating to 5–10 MW. per ton compared with 1·3 MW. per ton for the Calder Hall reactor. Sir John mentioned the more advanced reactor types—the Dounreay fast reactor, the high-temperature gas-cooled reactor and the liquid fuel reactor—and concluded with a consideration of other problems, including those of irradiation damage of the steel pressure vessels, and stress corrosion difficulties.

T. E. ALLIBONE

THE CHEMISTRY OF TERPENOID COMPOUNDS

A SYMPOSIUM on recent advances in the chemistry of terpenoid compounds, organized by the Chemical Society, was held in the Chemistry Department, University of Glasgow, during July 11–12. A marked feature of this symposium was the emphasis placed on ideas and methods which had scarcely entered the field even as late as 1950. Terpene chemistry was the first chemistry of natural products in which a wide range of related substances was examined, and the emphasis for many years was on structures. The first great generalization was the 'isoprene rule', which has recently been expanded into the 'biogenetic isoprene rule', and nowadays it is evident from the conference that chemists are not content merely to determine structures but wish to correlate these structures with those of the isoprenoid compounds in general. The term 'biogenesis' was mentioned in some connexion in almost every paper. Another feature was the universal dependence on physical methods for suggesting probable structures: infra-red and ultra-violet spectra and optical rotatory determinations are some of the chief tools used. Attempts at total synthesis of terpenoid compounds were described in only two papers.

The attendance at the symposium was international, with representatives from several countries including Australia, Canada, France, Great Britain, New Zealand, Switzerland and the United States.

The first paper, on the structure of the sesquiterpene ketone zierone (Prof. A. J. Birch, D. J. Collins, R. P. Hildebrand, A. R. Penfold and M. D. Sutherland), is an example of the use of newer methods based largely on absorption spectra. The substance is a derivative of a new natural azulene, and the chief method of structure determination was by dehydrogenation, by methylation at the carbonyl group and adjacent to it, and dehydrogenation, and then a study of the spectra of the resulting azulenes. Some probable conclusions can even be reached as to the stereochemistry of the whole molecule by a study of the spectra of dihydrozierone diol produced by osmic acid oxidation. Zierone is chiefly notable in that although it is isoprenoid one of the units is reversed from the normal head-to-tail linkage. In th[illegible] connexion also Prof. F. Sŏrm discussed the structure of acorone and laserpitine, both rather remarkable ketonic sesquiterpenes. The latter is an isocadalene derivative with one reversed unit, the former a spiro-diketone with a regular linkage, which by migration reactions of known type could be rearranged to an isocadalene derivative. It is suggested that it might in fact represent the type of linkage between the two series. The use of spectra was again well illustrated in a number of connexions, but notably in the observation that the infra-red spectrum of the fully reduced acorone showed the compound not to belong to any known series of bicyclic sesquiterpenes.

A paper by Prof. W. Cocker illustrates another aspect of the effect of light: its ability to isomerize some substances to interesting structures of higher energy-level. In this case the product obtained by irradiation of santonin in aqueous solution and its transformation products were discussed, and it was concluded that the initial product contains a cyclopropane ring. Among other use of spectra, the infra-red adsorption was used for counting the number of methyl groups present. It is an interesting speculation as to how far similar reactions in plants possibly catalysed by other substances may explain the production of 'improbable' compounds of this nature. Work on irradiation of santonin is proceeding in at least three other laboratories, and the symposium has no doubt facilitated the correlation of these researches. Other irradiation work was later reported by Dr. G. Büchi.

In a not too distantly related field, Dr. F. J. McQuillin considered the autoxidation of sesquiterpenes of the eudesmane series containing an αβ-unsaturated ketone system; similar products were obtained by the use of alkaline persulphate. With carboxyl groups in the correct position lactone rings can be produced in the same position as in santonin.

In this case the autoxidation was much influenced by the configuration of the side-chain.

A number of problems of triterpene structure were presented. Prof. E. R. H. Jones (with T. G. Halsall, W. J. Dunstan and H. Fazakerley) discussed the chemistry of hydroxyhopanone and concluded that it is pentacyclic, but they could not relate the nucleus to a known series. It is thought possibly to be related to zeorin. All the standard methods, including optical rotatory dispersion, were used in this work. Prof. G. Ourisson (with P. Crabbe, T. Takahashi and M. Palmade) used classical-type methods to elucidate the structure of dipterocarpol. This was converted to a steroid-hormone analogue (8β : 14α-dimethyl-18 nor-nortestosterone) which is biologically completely inactive. It was suggested that this is due to distortion by axial 8 : 18-methyl groups. The structure of katonic acid (3α-hydroxyolean-12-en-29-oic acid) was elucidated by Dr. F. E. King (with J. W. W. Morgan) by relating it to the β-amyrin series. The authors appeared not to know whether to be pleased with a comparatively easy solution of the problem or disappointed that something more fundamentally novel was not involved.

Prof. H. Erdtman (Stockholm), who was presented with the Flintoff Medal for his achievements in the field of chemical botany, considered very carefully possible uses of chemical constituents in taxonomy. The chief note sounded was of hope, tempered with caution, but obviously a great deal of work must be done before firm conclusions can be reached.

A totally different aspect of the subject was treated by Prof. E. Wenkert (with B. G. Jackson), who discussed the problems encountered in synthetic work in the tricyclic diterpene field. Although the original aim was not completely achieved, Prof. Wenkert in characteristic fashion turned to advantage apparently incidental observations to provide a reductive (lithium–ammonia) method for the hydrolysis of hindered esters, and in a brilliant exposition extended his biogenetic theories in postulating valid analogies between Friedel–Crafts reactions and biogenetic processes.

Another synthetic problem was discussed by Prof. R. A. Raphael in considering a most ingenious example of the indirect approach in work designed to lead up to the total synthesis of iridodial and related substances.

Natural diterpenes were not neglected. T. G. Halsall (with J. D. Cocker) described the structure and stereochemistry of labdanolic acid and discussed the possible biogenetic significance of the failure of diterpenes and triterpenes to occur together. Dr. W. B. Whalley (with Miss A. Harris, and Prof. A. Robertson) described work leading to the structure of rosono—and rosenono—lactones, the first fungal diterpenes to be structurally elucidated.

The structure of the complex bitter principle limonin, $C_{26}H_{30}O_8$, was discussed by Dr. O. Jeger, who was not sure whether it is a triterpene less four carbon atoms or a diterpene plus six carbon atoms. It contains a furan ring, two carbon rings, two lactones and probably two other ether (epoxide ?) rings. Several of its complicated reactions were formulated in a reasonable manner, and a race is now anticipated between organic chemists and X-ray crystallographers for a final solution.

Some extremely energetic three-dimensional musical chairs was involved in three papers dealing with very complex ring-structures. On the basis of this work there is certainly no need for natural-product chemists to be apologetic about their ability to deal with reaction mechanisms. Prof. A. Büchi confirmed the structure of 'carvone camphor' obtained by illumination of carvone, and showed that it contains a cyclobutane ring the presence of which leads to most interesting rearrangements. Prof. K. Wiesner (alkaloids from *Aconitum napellus*) and Prof. R. C. Cookson (with M. E. Trevett) (delpheline) showed that terpene chemists will in future have to take into account the chemistry of nitrogen. The beautiful and complex three-dimensional networks discussed require a three-dimensional mind to cope with them. The reporter was feeling two-dimensional at the time.

The use of infra-red spectra in all the preceding work was appropriately emphasized by Dr. R. N. Jones, who discussed a new method for use with micro-quantities. He also described some potential uses of the method of 'subtracting' spectra.

From the scientific point of view, including selection of subjects, methods of presentation and general smooth running, the symposium was the most successful the author has attended. The high attendance to the last word, and generally expressed opinion, confirm this impression. Discussion was lively and interesting, with particularly notable contributions from the United States. Several very enjoyable social occasions were also provided: a dinner in the beautiful loch and hill country of Aberfoyle, and a Scottish evening with Scots songs and dances and other characteristic Scotch products was attended by kind invitation of Imperial Chemical Industries (Nobel Division). The organizing committee is to be heartily congratulated, and thanks are particularly due to Dr. A. Payne, the local representative of the Chemical Society. A. J. BIRCH

SCIENCE TEACHING AT KING'S COLLEGE, TAUNTON

ON July 6, H.R.H. Princess Margaret opened a new science block, consisting of four laboratories, two preparation rooms and a science library, at King's College, Taunton. Incorporated in the front of the new building is a memorial gateway to those Old Boys of the College who gave their lives in the Second World War.

There is in the nature of the memorial a special significance for those connected with the College, for King's was probably the first school in Britain in which science was seriously taught. The person responsible for this early start was the Rev. William Tuckwell, headmaster of Taunton College School, as the school was then called, during 1864–77. When Tuckwell was first appointed head, the school was situated in the old buildings erected in 1522 by Bishop Fox. They are now Taunton's municipal buildings. Within a year of his acceptance of the post, Tuckwell had bought the land where the school now stands, south of Taunton. The site was acquired in 1865 and the new buildings opened in 1870. Tuckwell had introduced the teaching of physical science in 1865 and he built his laboratory in 1869.

An eminent botanist and a scholar of English literature, Tuckwell wrote books on both these subjects, and, during his term of office as headmaster, delivered a course of public lectures and read papers on the teaching of science before the British Association. His revolutionary ideas met with much reactionary opposition among the classically prejudiced. In his paper "Science-teaching in Schools", read before the British Association at Exeter in 1869 (which was published in the first issue of *Nature*, November 4, 1869) he stated, referring to his science pupils, ". . . they will pass out into the world immeasurably superior to their contemporaries who know not science, with doors of knowledge opened which can never again be closed; with a fund of resource established which can never be exhausted; with minds in which are cultivated, as nothing else can cultivate them, the priceless habits of observation, of reasoning on external phenomena, of classification, arrangement, method, judgment".

Tuckwell held that the syllabus should include two years of mechanics, two years of chemistry and one year of botany, and that any further time at school should be spent studying physiology. He recommended that three hours of science should be taught each day. For the teaching of mechanics, he maintained that the necessary apparatus should include ". . . a good air-pump, a set of pulleys, models of the force-pump and the common pump"; using as a text-book Newth's "Natural Philosophy". He took his pupils on visits to various 'manufactories', because he believed that they ought to have practical knowledge of the application of this apparatus in everyday life.

For chemistry he considered a laboratory essential: ". . . No matter how rough or shabby a room, so that it will be well ventilated, have gas and water laid on, and will hold from sixteen to twenty boys . . .". His benches cost about £4 each. ". . . The general laboratory stock, including a still, a stove or furnace, gas jars, a pneumatic trough, a proper stock of retorts, crucibles, tubing, etc., and the necessary chemicals will cost under £12. Each pair of pupils must have also between them a set of test tubes, a washbottle, a spirit lamp . . . and twenty-four bottles of test solutions, while each boy has his own blowpipe, tripod and stand, pestle and mortar, and three beakers. These will cost each boy about eight shillings. . . . The text-book used should be Roscoe's, or Williamson's, and a large black board is quite indispensable . . .".

He suggested such books as Lindley's "Descriptive Botany" as a text-book for botany; and for botanical experiments, he thought that ". . . every boy should be furnished with a small deal board, a lens, and a sharp knife . . . Flower trays . . . should be kept constantly in use . . . Their cost per tray, holding eighteen bottles, is under two shillings . . .". He also deemed it necessary to possess a skeleton, the cost of which he estimated at £5.

Tuckwell also thought that schools studying science should have a set of meteorological instruments, which he estimated would cost between £16 and £20. Also he suggested that a special room should be devoted to the collection of scientific specimens, such as minerals, fossils, zoological specimens and physiological preparations; the driest corner of the room he assigned to the herbarium. He recommended a small library and a botanical garden.

He probably put some of these ideas into practice even when

BRITISH ASSOCIATION MEETING IN DUBLIN

TECHNOLOGY AND WORLD ADVANCEMENT*

By PROF. P. M. S. BLACKETT, F.R.S.

President of the British Association

I

SCIENTISTS have often been reproached for not concerning themselves sufficiently with the effects—for good or ill—of their discoveries on society. This charge can scarcely be laid against recent presidents of the British Association. Most of my illustrious predecessors of the past decade have dealt in one way or another with the impact on contemporary society of the vast eruption of scientific and technological discovery, which is by far the most historically significant facet of our epoch.

Last year a special committee was appointed by the Council of the Association to re-formulate the Association's objectives in the light of present-day conditions—so different from those of 1831, the year of our founding. One of its recommendations was that still more stress should be laid on the social consequences of modern science and technology. I think that this advice is wise. However, I cannot deny that to follow it is to risk becoming controversial. I do not mean controversial over matters of scientific fact and theory, but controversial in a plain political sense.

For in science and technology lies the key to wealth; and the creation and distribution of wealth are the warp and woof of the many-patterned texture of politics. Many scientists and engineers—let us be quite frank about it—have in the past deliberately avoided thinking more than they can help about the social consequences of their collective achievements: just because, to do so, would sweep them into the troubled waters of political controversy. Some of our scientific predecessors were far less inhibited. It is worth recalling the forthright dictum in 1802 of the young Humphry Davy: "The unequal division of property and labour, the differences of rank and condition among mankind, are the sources of power in civilized life, its moving causes and even its very soul". Davy, who has been called the major prophet of the new class of applied scientist, had no scruples about expressing frankly his views on a major problem of his day. I will try to emulate his forthrightness in expressing my views on what seems to me to be the major and very different problem of ours.

It has often been held that the development of natural science and technology gives rise to political controversy only because of the backwardness of the social sciences. If the social consequences of technology, and indeed the problems of society in general, could be studied with the same objective impartiality which has worked such miracles in the physical world, then, so it is alleged, much of the sordid controversy of politics could be avoided.

This is less than half a truth. While all will echo Lord Adrian's plea at Oxford in 1954 for a more rapid development of the social sciences, one must be clear about their limitations. The facts discovered by social scientists—including economists—and the theories which they elaborate, cannot by themselves define the objectives of social policy: what the goals should be must ultimately rest on a judgment of values by individuals. Such judgments of priorities, when made by social groups, become political programmes.

When technological advance increases a nation's power to produce wealth, how should this be used? How much should be devoted to more material goods and how much to more personal leisure and to gracious living; how much to providing greater consumption now and how much should be set aside for the future; how much to greater opportunity for youth and how much to greater security or luxury for old age? How and to what extent should different kinds of ability and enterprise be rewarded? The social scientist can assist us to think rationally about such alternative uses for our material wealth and may help us to attain any end we choose; he cannot make the choice for us.

II

Though few to-day in the rich Western world are naïve enough to think that an increase of material wealth necessarily results in a corresponding increase of human happiness and personal fulfilment, yet few would deny the validity of using a nation's material wealth as a measure of its potential welfare.

One of the most striking features of our contemporary world is the very uneven distribution of material wealth. Leaving aside the countries in the Soviet orbit, as needing separate discussion which will not be attempted, we have at one extreme the highly industrialized countries of Europe and of North America and Australasia, with, in round figures, a population of 400 million, and an average income a head of £300 a year (at 1949 prices). For Europe alone the average is £200 a year. Within this group of relatively rich Western countries there is, of course, a wide range of average income, from one-third to more than double the average. Three hundred years ago, the pre-industrial countries of Europe had a real income a head of not much more than one-tenth of what it is to-day. In the past half-century their wealth has been increasing at a rough average of nearly 2 per cent a head every year, thus doubling in rather less than forty years. This huge and historically rapid rise in individual wealth has been accompanied by a very large rise in population.

---

* Presidential address delivered in Dublin on September 4 and appearing in the September issue of the *Advancement of Science*.

In marked contrast to the rich West are the still pre-industrial countries, particularly those of Asia, Africa and South America. These—excluding Soviet China—have a population of some 1,000 million people and an average income of about £20 a year a head, that is, one-tenth that of Europe and a still smaller fraction of that of the West as a whole. Moreover, this low income does not on the average seem to have increased much during the past three centuries and may at times have fallen, despite the revolutionary improvements in world technology as a whole during this period. It seems from such figures that 300 years ago the standard of life in at least the most advanced nations of the East, such as China, India or Persia, must have been as high as that of Europe. The gap now of ten to one in favour of Europe is of quite recent origin and is due to the sudden advance of the West, mainly in the past 200 years, whereas the Eastern countries have remained nearly static.

Economists have recently been turning their attention to the complex historical causes which lead a country to transform itself from a static pre-industrial State to a growing industrial one. Making apt use of an aeronautical metaphor, the American economist Rostow has named this vital period of transition 'the take-off into sustained growth'. In Britain, the first country to become fully industrialized, this critical period seems to have been the last twenty years of the eighteenth century.

In a typical pre-industrial country, three-quarters or more of the population may be engaged in agriculture, and wealth tends to remain constant or rises but slowly. Savings and gross investment are low, some 5 per cent or less of the national income, that is, only about enough to maintain a static economy by paying for the depreciation of existing wealth. After 'take-off', savings and gross investment rise until some 15 per cent of the national income is available for gross investment, leaving around 10 per cent for net new productive investment. On the average in the West to-day such new investment results in a rise of total income of about 3 per cent a year. Allowing for the population rise of some 1 per cent, this gives an increase of wealth a head around 2 per cent a year. The fraction of the population engaged in agriculture steadily falls as social development and industrialization proceed, and agriculture itself becomes partly industrialized and so much more efficient. In Britain, the savings and investment required for the 'take-off' were essentially provided by the prosperous classes, who did not spend their surplus wealth on ostentatious living but invested it in productive industry. It is to this fact which Humphry Davy referred in the remark I have quoted.

Everyone recognizes that most scientific and technological innovations can lead to continually increasing wealth only when they become embodied in material things, particularly production goods such as machine tools, chemical and fertilizer plants, transport and communication systems. Nuclear power, the outstanding technical development of this decade, adds to wealth only when nuclear power stations have been built. However, the large amount of capital required is not always appreciated, especially by scientists and inventors, who naturally wish to see their discoveries and inventions used. For heavy basic industries such as steel, oil refining or heavy chemicals, a capital of £5,000–£10,000 a man employed is required; for medium and light manufacturing industries perhaps £1,000–£3,000. Such sums must come from government, corporate or personal savings, that is, at the expense of present consumption; or, alternatively, from external loans. The high capital cost of industrialization is the main reason why the 'take-off' is such a difficult operation for the pre-industrial countries. This is especially so at present because most production goods must be imported, thus making heavy demands on foreign exchange, which, except in a few oil- and mineral-producing countries, is chronically short.

In addition to maintaining its existing wealth, the Western world is saving and investing productively some 10 per cent of its income of £300 a year a head; that is, some £30 a year a head is being invested in additional plant and machinery to create more wealth. The pre-industrial countries of Asia only have about £20 a head to live on, that is, for both consumption and production goods. The West is thus saving more than the East is spending on everything. No wonder that the gap in wealth between the West and Asia is steadily widening. Moreover, most new scientific and technical discoveries or developments tend to widen the gap still more, just because the already rich countries have the capital to make full use of them, but the poor countries have not. For example, under present conditions, the advent of nuclear power must tend to widen the absolute gap still further, because of the high capital expense of nuclear power stations. Decidedly, scientific and technical invention is no fairy wand to wave over a poor country to transform it into a rich one.

III

Anyone who wishes to make himself familiar in detail with the degree of poverty of the under-developed countries of the world, particularly those of South-East Asia, India, Pakistan, Ceylon, Burma, Indo-China and Indonesia, will find abundant material at his disposal. In recent years there has been a spate of blue books, white papers, newspaper leaders, speeches, tracts and academic treatises in which can be found statistics, eloquent writing, moral and political fervour. Of special importance were President Truman's 'Point Four' in his inaugural speech in 1949, and the Colombo Plan in 1950.

When after the Second World War these countries threw off alien rule, the ills of South-East Asia—poverty, underfeeding, disease and illiteracy—became important factors in international relations. These new independent countries became free to make their own external and foreign policy, based on their own views of their own interests. They can now choose for themselves with which countries they will trade or with which they will have close diplomatic or military relations. Moreover, no political party in these new Asian countries can hope to maintain itself long in power if it does not succeed in improving the lot of its people. The pre-industrial countries of the East can only become less poor by saving and investing money in better education, agriculture, social services and industrialization. If they are to do this out of their own resources alone, they must inevitably increase their poverty temporarily.

Several careful investigations have been made of the needs for external financial aid in the form of long-term loans and gifts to enable all these 'have-not' countries to make a good start on the road to prosperity. It seems that the immediate need is not far from the round figure of £1,000 million a year, that is, £1 a year for each of the 1,000 million inhabitants of these countries. It is difficult to ascertain the amount actually made available for other than defence purposes from the Western nations under the various aid schemes, such as the Colombo Plan, the Colonial Development projects, technical aid through the United Nations, and through various bilateral agreements. Though quite considerable, the amount is almost certainly only a fraction of the above requirement.

Since, of all the former dependent countries, India has the best worked-out plan of social advance and, moreover, is much the largest, it will be convenient to discuss her situation in some detail. Many of the problems facing India are common to other underdeveloped countries, whether in South-East Asia, Africa or South America. The Planning Commission in New Delhi is aided by a powerful statistical and economic group in Calcutta, presided over by a mathematical statistician, Prof. P. C. Mahalanobis, Fellow of the Royal Society of London. This research group has been assisted by economists from both Western and Soviet countries in the study of the problem of how India can most easily, quickly and painlessly emerge from the nearly static and essentially pre-industrial state in which she found herself on attaining independence in 1947.

During the period of the first Indian five-year plan ending in 1956, the national income rose by 18 per cent. This is an important, even if precarious, achievement, in marked contrast to the stagnation of the previous decades. In the second five-year period, 1956–61, a rise of national income of 25 per cent is planned, that is, 5 per cent a year. Whether India can achieve this without additional external financial aid is now doubtful, especially in view of her present large deficiency in her balance of payments. The plan involves not only attaining the high rate of new productive investment of at least 10 per cent of the national income, but also an annual return of 50 per cent in terms of additional output on the capital invested. Such a high net marginal return on capital can only result from very wise planning and efficient execution of the overall pattern of development. Allowing for the population rise of 1·3 per cent a year, the planned rise of income a head is 5 per cent minus 1·3 per cent, or 3·7 per cent a year.

Such a rate of rise, if achieved, would be nearly twice the average of Western Europe at the present time. So the relative gap, that is, the ratio between the living standards of India and of Europe, would slowly begin to close. But how slowly! If these rates continued, nearly half a century would elapse before the living standard of India would climb from one-tenth to one-fifth of that of Europe. Moreover, the actual difference between the living standards, that is, the absolute gap, would still widen; for example, if the assumed rates of advance are maintained for the next ten years, the rise of annual income of a European will be much more than the final income of an Indian.

The limit of India's possible rate of advance is set mainly by the available capital for productive investment, and particularly of foreign exchange to buy production goods from other countries. Failing massive external aid, the advance is limited to what a democratic parliamentary government of a very poor country can raise internally by taxation and loans.

It is clear that the population problem looms especially large to those who are pessimistic about the possibility of rapidly increasing material wealth, including food. Historically the population of Europe in the nineteenth century rose faster than that of Asia; but no population or food problem arose because wealth, including food, rose much faster. The population of the United States to-day is rising faster than that of India. As we have seen, the rise of population in such countries as those of South-East Asia does add, in a defined and calculable way, to the cost and burden of achieving economic progress. However, it is a not uncommon error among Westerners to assume implicitly that no marked economic and agricultural progress in these countries is possible, and so to be led to view them wearing social spectacles through which little can be seen but millions of brown babies.

It is interesting to note that both the Governments of India and China have started to take steps to reduce the population rise. Success in these movements towards reducing the rate of rise of population can only be achieved by education, which itself depends on increasing wealth, and this can only come from industrialization. Moreover, increasing industrialization, as part of a general social advance, is the key to increased efficiency of agriculture and so to a greater food supply. Rural education, transport, power supplies, irrigation, agricultural machinery, fertilizers, pesticides and improved seeds are the essential factors.

IV

What is the historic origin of the astonishing differences to-day between the economic and social conditions of the West and the East? A whole host of hypothetical causes have been advanced: differences in natural ability, climate, health, food, natural resources, religions, social systems or methods of government. To attempt an answer to this problem it is necessary to look deeply into history.

Archæologists and historians have now made it possible to grasp the rough outlines of the history of technology. Since this term means 'the science of the industrial arts', and since it is by these arts that the material goods of life are produced, the history of technology can almost be equated with the history of the material aspects of civilization. With the recent publication of the first two volumes of the "History of Technology", with Charles Singer as editor-in-chief, the layman can easily survey in some detail, though with many gaps, the history of clothes, textiles, jewellery, cities, houses, temples, arms and armour, vehicles, domestic animals, crops, writing, sculpture and pottery, from the emergence more than 5,000 years ago of civilized urban life in the river valleys of the Nile, Euphrates and Indus, up to the present day.

Abundant evidence proves the high level of technological achievement at a very early date. The astonishing building feats of the Egyptians and Mesopotamians are world-famous. Less widely known are the gigantic town-planned cities of northern India, such as Mohenjo Daro which flourished more than 4,000 years ago, with their main drainage systems, vast granaries, and citizens' houses far better than those lived-in by most Indians to-day. Innumerable examples abound in our museums or are illustrated in our histories, demonstrating the astonishing technical triumphs of antiquity. The stern beauty of the 4,000-year-old bronze head of Sargon the Great, or the overpowering grandeur of the 3,000-year-old inner coffin of Tutankhamen, alone suffice to prove that the highest artistry was allied to superb technical skill. The modernity in design of many articles of domestic use in ancient times is most striking. A wooden chair or a manicure set from the Egyptian New Empire of 1000 B.C. would not look out of place in the most up-to-date shop-window to-day, and might well be better made. A high level of domestic culture was by no means restricted to a few monarchs and officials. The cities of Crete, Babylonia and Egypt around 2000 B.C. must have abounded in comfortable and cultivated people who led very pleasant lives, almost as refined and luxurious as prosperous people enjoy to-day. In the material arts of life one is constantly impressed by the absence of many major improvements between the height of the great Middle and Far Eastern Empires and the rise of modern technology in Europe about the eighteenth century A.D. Except for the past two hundred years, Rudyard Kipling was not far wrong when he wrote :

> "We tell these tales, which are strictly true,
> Just by way of convincing you
> How very little, since things was made,
> Anything alters in any one's trade."

Slow and steady progress, of course, occurred in some fields, retrogression in others. Among the most important technological innovations since ancient times were firearms, the magnetic compass, printing with movable type, the horse collar, improvements in wind and water mills, and ocean-going ships. The first three were European medieval developments of much older Chinese discoveries which had never before been exploited fully. They all predated the scientific revolution which only began around 1600, and thus belonged to the ancient craft tradition.

The contribution of China to the history of technology is only now beginning to be revealed, particularly by Joseph Needham and Wang Ling in "Science and Civilization in China". Far Eastern technology appears to have been supreme between 500 B.C. and A.D. 1500. Belief in Europe of the technological superiority of the Far East was indeed widespread from Marco Polo in the thirteenth century to the French missionaries of the eighteenth. The wealth of the Indies was proverbial. Venice—"once did she hold the gorgeous East in fee"—grew rich by trading in textiles, spices, porcelain and jewels.

During the first two hundred years of modern science, from 1600 until 1800, science learnt much from technology, but taught it relatively little. The empirical industrial arts were already so highly developed, and indeed had been so for thousands of years, that systematic science had to develop far before it could improve decisively on pre-scientific technology. Even to-day, the biochemist cannot teach a chef how to prepare a better omelette. Despite the interest of the Royal Society in the 'useful arts', it was not until the last quarter of the eighteenth century that the impact of science on technology began to be decisively important.

The vast developments from the seventeenth century to the present day have been almost exclusively a Western achievement. Though the technological foundations on which Europe built arose mainly in the countries of the Near and Far East, these have scarcely shared as yet in the later scientific and industrial revolution.

To the question why what happened did happen, I do not think there is an agreed answer. Certainly it had nothing to do with any inherent European superiority—indeed, the history of the previous millennia might well have suggested the opposite. Most probably it was differences in social and economic organization which were the decisive factors.

Among the positive factors was certainly the growth after the eleventh century of the city states of Italy, followed by the free cities of northern Europe, where merchant entrepreneurs were free from many of the restrictions of feudal society. Not noble but not poor, these men, much like the Ionians of Thales's time 2,000 years earlier, had a pecuniary interest in exploration and in technical innovation. This positive drive towards technological and social change in Europe might not have been sufficient to produce much more than a temporary spurt of pre-scientific technological advance had it not been for the scientific revolution which in the seventeenth and eighteenth centuries grew out of it.

An essential prerequisite for the scientific revolution was the weakening of the opposition of organized religion to the free play of scientific experimentation and speculation. As R. H. Tawney has shown, by the last half of the seventeenth century Europe was weary of a century and a half of religious strife. Religious tolerance first grew in the merchant cities, where it was found essential for trade. Intellectual tolerance followed in its wake. When the Civil War in Britain ended with the victory of the technologically progressive cities and merchant classes over the still feudally inclined monarchy and aristocracy, Britain was free from restrictions both on scientific thought and on the use of money for profitable and speculative investment. The way was clear for Britain to become the first industrial nation and to usher in our present scientific–technological age. However, even in these favourable circumstances the necessary conditions for the 'take-off' did not exist until the end of the eighteenth century. The parliamentary system of government, which is Britain's proudest political achievement and still a major export, arose in mature form out of this long struggle against privilege and restriction.

One notices that the conquest of Asia and America by Europe was largely completed before the scientific revolution. It was Western superiority in the pre-scientific technology of firearms and ocean-going ships which formed the material basis of the rise of the European empires in Asia and America. Europe was then passing through one of those periods of intense and ruthless energy, both mental and physical, which occur, for complex reasons, from time to time in the history of mankind.

Just when Europe was in a crusading, expansive and aggressive mood, the once great Indian Mogul Empire began to disintegrate, as so many empires have done in the past. Portugal, Holland, France and Britain fought long and bitterly for the spoils. Finally India, Burma and Ceylon fell to Britain, Indonesia to Holland, and Indo-China to France, to be governed from Europe until they acquired their independence after the Second World War. China, though humiliated and partially occupied, never came completely under Western dominance. The vast Chinese Empire seems to have been too rigid to change of its own accord, but survived mainly because of the bitter rivalries between the Western Powers. Japan alone of Asian nations both accepted Western technology and avoided Western dominance. In fact, for a time she beat the West at her own game by achieving a more rapid rise in income than any West European country before or since, and reached a wealth per head at least as high as that of the poorer countries of Europe. This success had a profound effect in those Asian countries which were struggling at that time to be free from Western dominance.

The impact of the West on some of the static or declining pre-industrial civilizations of Asia brought about certain fundamental changes essential to social advancement, including the weakening of the power of the old feudal aristocracies, the growth of a merchant class, the introduction of Western education, science and medicine, and in some cases the beginnings of a modern industrial and transport system. However, in no Asian country except Japan was the 'take-off' achieved.

It is notoriously hard for Westerners to regard with detachment the long period of European ascendancy in the East. With the fading of the ascendancy, objectivity is becoming easier, and the West has no longer any excuse for not appreciating the Asian point of view. The Indian scholar-diplomat, K. M. Pannikar, in his recent book "Asia and Western Dominance", tells the story of the relations between East and West from Vasco da Gama's landing at Calicut in 1498 to the present day. The reader who meditates on some aspects of the story will be inclined to adapt an old aphorism originally applied nearer home and say 'History is something that Europeans should remember and Asians should forget'. In truth, most Asians have, or politely pretend they have, and this is in no small part due to Britain's freeing of India, Pakistan, Ceylon and Burma after the War: in my view, one of the greatest single acts of British statesmanship of this century. It is, I think, a tribute to both the Indian and British peoples that after decades of bitter political struggle, personal relationships between Indian and British individuals are closer than ever before. It is important, however, to remember that most South and South-East Asian countries attribute much of their present backwardness to Colonial rule. This was a constant theme at the recent conference at Bandoeng of the representatives of 1,500 million coloured people.

V

After 2,000 years of relative stagnation of world technology, Europeans staged a scientific, technological and industrial revolution which has transformed within three centuries, and is still transforming, both the material way of life and the mental outlook of mankind. This astonishing achievement of the peoples of Europe must rank with the greatest events of world history. During the centuries when European scientists, technologists and craftsmen were conquering Nature, European fighting men, missionaries, traders and administrators were conquering the world. By the close of the nineteenth century a hundred million Europeans were ruling some 700 million people in Asia, Africa and America.

Understandably, this double and interrelated triumph of the West over both Nature and the world went to its head. By the last half of the nineteenth century the doctrine of the innate superiority of the white peoples, with its corollary of the inferiority and incapability of coloured people, had become widely accepted in the West. To a great extent, white racialism is economic and administrative in origin. Men tend to feel superior to those whom they rule and to despise those whom they exploit.

What has science to say of the innate mental differences between the different races of mankind? Rather little, it seems—at any rate so far. The physical differences of colour, features and stature are obvious without the aid of scientific study. It may well be that innate differences of mental make-up do exist: but scientific study has failed as yet to establish their existence or nature. Moreover, even if mental and temperamental differences could be demonstrated as innate in such qualities as courage and determination of purpose, physical strength and skill, or in musical, literary, artistic, mathematical and analytical power, between the individuals of different races, the attempt to rate different races in an acceptable general order of merit is foredoomed to failure. For no agreement would be obtainable on the relative weight to be attached to the various abilities; indeed, the various human qualities have different values in different environments.

Even if further studies should show marked differences now between different races, it would be as dangerous to extrapolate too far forward into the future, just as the history of technology has shown it to be dangerous to extrapolate back into even the relatively recent past. The artistic and technical triumphs during the Middle Ages of Peru, Mexico, India, Indo-China and China are a perpetual reminder that great creative ability and immense energy have appeared quite recently among many different peoples, with diverse social systems and religions, and vastly different climates. The grandeur of Cusco, Chichen-Itza, Fatehpur-sikri, Angkor Vat and the Forbidden City in Pekin are permanent memorials of not very distant achievements of the coloured people of the world.

I am convinced that Western pessimism about the possibility of social advance by ex-colonial Asian countries is both unjustified in fact and a serious cause of practical error. It has led the West to over-estimate the need of the 'have-not' countries for technical advice from Western experts and to under-estimate the need for simple financial help. Admirable as many of the schemes of technical aid have been, particularly those in education, medicine and agriculture, the sending of experts to poor countries without the capital to carry out their plans could be as irritating as to send a trained cook to a family unable to pay the baker. In so far as expert aid by Western technical personnel is needed by an under-developed country, it is usually both more efficient and cheaper to provide money for the country itself to hire those whom it needs. Unless followed up by massive financial help, some of the West's present aid programme may yet merit the war-time wisecrack of 'offering all aid short of help'.

What would constitute real help? The figures already given suggest that in addition to likely commercial and government short-term lending, an additional £1,000 million a year is needed as a free gift or as long-term loans from the 400 million rich

Westerners to the 1,000 million Asians, Africans and South Americans in the under-developed countries outside the Soviet orbit. To the Western donors, this would amount to a levy of less than 1 per cent of their income; Britain would pay £150 million a year, and this would only postpone by less than a year the expected rise of 50 per cent in British living standards over the next quarter of a century.

To the recipient country, it would mean £1 a year a head in foreign exchange, that is, a 5 per cent addition to their income of £20 a year. If wisely invested, this should allow the standard of life to rise at rather more than an extra 2 per cent a year. It would therefore make an appreciable contribution to the outstanding problem of the now widening gap.

Such aid to a nation with a well-developed national plan would probably not be needed for more than a limited period, perhaps one or two decades. By then she should have achieved the 'take-off' and be in a state of sustained economic growth, able to dispense with outside aid. Extending the aeronautical metaphor, the suggested Western action would amount to using its great wealth and material power to give the 'have-not' countries an 'assisted take-off'. It must always be remembered that without a strong and intelligently directed internal drive for social betterment, no country can achieve much. Outside aid can only help fully those who are already prepared to help themselves to the limit of their capacity.

Some may think I have taken a too severely economic attitude to the problem of the 'have-not' countries and have neglected the more spiritual factors. Undoubtedly the citizens of a static pre-industrial country may possess many qualities such as contentment, humility, kindness and gaiety in greater measure than those of a rich and progressive country. Though this is true, it is a doctrine which the restless and prodigal West might well preach to itself rather than to others. With nations, as with individuals, the ultimate hypocrisy of the rich is to preach the virtue of poverty to the poor.

VI

The essential fact of the present-day non-Soviet world is that the huge gap of material living standards between the industrial and the pre-industrial countries is steadily widening. Moreover, most new technological advances tend to widen it still further. If present tendencies were to continue for many decades, then one would find many of the ex-colonial and similar countries still largely pre-industrial and so very poor. On the other hand, the vast acceleration of technological progress in the West will be leading the most advanced of the industrial countries to pass progressively, if they so wish, through the phase of the four-day week, on the road perhaps to the final bliss, or ultimate boredom—according to temperament—of the five-day week-end. The difference to-day in material wealth cannot be primarily attributed to differences of national or racial aptitudes, but has complex historical origins. Moreover, the gap in wealth is now so great that an important contribution to narrowing it could be achieved at a relatively small cost to the rich industrial countries.

In turning to consider whether the Western world should make this sacrifice, we leave the field of social analysis and enter that of political and moral controversy. Some people will stress the long-range political dangers of the widening gap and that the survival of parliamentary systems of government in many of the under-developed countries may be dependent on the achievement of rapid social progress. Others will lay most weight on military considerations, arising out of the polarization of so much of the world into Soviet and anti-Soviet blocs. If the West does not help, perhaps the Soviet bloc will. This has hitherto been by far the strongest stimulus to what Western aid has been forthcoming. Strong economic arguments can be produced: poor countries are also poor markets for manufactured goods, and may be unreliable suppliers of essential raw materials: such 'enlightened self-interest' is particularly relevant for Britain with her essential dependence on overseas trade. Some of the strongest motives for a substantial aid programme arise from moral and religious values. Many feel that such large differences of wealth, health and opportunity are wrong, and that to work to reduce them would give a new sense of moral purpose to the West. Recently Ritchie Calder has aptly suggested that massive Western aid to Asia might be considered as reverse lend-lease for the incalculable debt which the West owes to the East for the age-old gift of the great tradition of empirical technology which was the essential basis of Western triumphs. One might add—for it is often forgotten—that all the great religions of the world are of Asian origin.

Here are motives enough for each of us to weigh and make his choice. My own view is clear. I think the West should make the great experiment of sacrificing some of its immediate prosperity to give massive aid to the 'have-not' countries. To give this aid would not, I believe, prove very painful and it may do us a power of immediate moral good and, ultimately, of material good as well. If the major nations of the West cannot agree quickly to provide the required £1,000 million, then I would hope that Britain would 'go it alone' and make her contribution of £150 million a year available to her former Colonies, in addition to what she is already doing. In holding this view, I do not forget the many economic and social problems nearer home which need urgent attention.

Scientists and technologists have a special responsibility in this matter, since it is their genius and their skill which alone can bring the material basis of happiness within the reach of all. The progress of the natural sciences, the West's greatest achievement, has been based on experiment. Let us make now this great social experiment to spread the benefits of our labours. At present they reach only a few. A 'have-not' country, bound like a modern Tantalus by the chains of its lack of capital, gazes with unquenchable thirst on the growing riches of modern technology which it cannot enjoy.

Times and problems have changed since Humphry Davy commented so shrewdly on the social state of Britain at the very start of the industrial revolution. I will end this lay sermon—for this is what this address has become—by attempting to transmute his words to suit the contemporary scene:

The uneven division of power and wealth, the wide differences of health and comfort among the nations of mankind, are the sources of discord in the modern world, its major challenge and, unrelieved, its moral doom.

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS

STELLAR ENERGY AND STELLAR EVOLUTION

PROF. T. G. COWLING, in his presidential address to Section A (Mathematics and Physics), points out that, until a few years ago, ideas about stellar evolution had to be regarded as mainly speculative. Nearly every possible direction for stellar evolution has had its supporters. Some supposed that massive stars steadily lose mass, and evolve into less-massive forms; others that small stars can grow into massive ones by accreting material. Some thought that giant stars were newly created, and still in the process of gravitational contraction; others that they were stars which have been blown up from smaller radii during their evolution. All these suggestions rested to some extent on observation, and a fresh idea had to be imported before one could distinguish between them.

This idea has been provided by the recognition of the mode of generation of stellar energy. Nuclear processes provide the only source of energy adequate to keep the stars going; moreover, one type of nuclear fusion, in which hydrogen is built up into helium, can function sufficiently fast at temperatures like those met in the central cores of stars (15–25 million deg. K., say) to be able to maintain stellar radiation. Two helium-building processes are important. The first is the carbon–nitrogen cycle, in which a carbon-12 nucleus captures protons and is converted successively into carbon-13, nitrogen-14 and nitrogen-15; a final capture of a proton leads to a fission yielding the original carbon-12 nucleus and a helium nucleus. The second is the proton–proton process, in which protons are built direct into helium nuclei through steps involving first the production of deuterons and helium-3 nuclei, and then the combination of two helium-3 nuclei to form a helium-4 nucleus and two protons. The first reaction is probably dominant in stars appreciably more massive than the Sun, the second in the Sun and all less massive stars. Stars which have exhausted nearly all their hydrogen can generate energy by burning helium into carbon at a temperature of about 150 million deg. K., but this provides only one-tenth as much energy as helium-building.

Helium-building cannot maintain the radiation of stars 1,000 times as bright as the Sun for more than a small fraction of the time that the solar system is known to have existed. Thus among very bright stars obvious signs of evolutionary changes should be detectable. This agrees with recent observations of globular clusters, which are aggregates born even earlier than the Sun. These possess no very bright blue stars; those initially present have burnt themselves out long ago. The brightest stars in them are greatly distended red giants; such giants accordingly are stars well advanced in evolution, which have burnt much of their hydrogen. This conclusion is confirmed by the theory of stellar structure, which can explain the enormous radius of a red giant only if it has a core the molecular weight of which is greater than that of the rest of the star—a core where all the hydrogen has been burnt into helium.

After the red giant stage stars probably contract again. The stellar graveyard is usually supposed to be peopled by the enormously dense but very faint white dwarf stars. Before they can reach this state, massive stars must lose a large part of their mass, either by continuous ejection or explosively. This part of the course of evolution is not yet fully understood. But we are, generally, in the exciting stage of fresh discovery; speculation is being replaced by established fact.

CHEMICAL APPROACHES TO THE INVESTIGATION OF LUNG CANCER

IN his presidential address to Section B (Chemistry), Dr. J. W. Cook directs attention to the very large increase in lung cancer over the past few decades, and to the close statistical relationship which has been established in a number of investigations between the incidence of the disease and the smoking of tobacco—particularly in the form of cigarettes. He points out, however, that there is a legitimate difference of opinion on the interpretation of this statistical evidence. Some authorities believe that the relationship is a causal one; others consider that a causal connexion has not been established and that other factors, such as atmospheric pollution, industrial hazards and even psychological trends among smokers, are important. A decision between the various points of view would probably be best reached by a direct experimental approach to the problem, and it is this consideration which lies behind investigations of tobacco smoke which are now being carried out.

Attempts are being made to demonstrate the carcinogenic activity of tobacco tar experimentally. With cigarette tar produced in a machine designed to simulate human smoking, Wynder and his colleagues have succeeded in obtaining malignant skin tumours in mice and also in rabbits, and Wynder and Wright later found that the active material is contained in the neutral fraction. The tar is evidently a very weak carcinogen, for the experiments had to be continued for many months before tumours arose, and if it was diluted only two or three times, no tumours were obtained.

The active components of the tar have not yet been definitely identified. The known carcinogen, 3 : 4-benzpyrene, has been detected, but the amount found (1–2 parts per million) is considered too small to account for the activity of the tar. Another carcinogenic hydrocarbon found in the neutral fraction is 3 : 4–9 : 10-dibenzpyrene. Another suspect, arsenic, has been found in varying, but always very small, quantities.

Other constituents already recognized in tobacco smoke include hydrocarbons, both aliphatic and aromatic, alcohols and phenols, aldehydes and ketones, acids, nitrogenous compounds including nicotine and its degradation products, and inorganic constituents. The paraffin, *n*-hentriacontane, has been found in smoke and in tobacco itself, and it has been suggested that this hydrocarbon and others like it present in the tobacco wax form the main source of the aromatic hydrocarbons in the smoke.

Polycyclic aromatic hydrocarbons occluded in the soot in the atmosphere have also been considered as a cause of the increasing incidence of lung cancer, either acting alone or in conjunction with cigarette smoke. Goulden and Tipler estimated about 300 mgm. of benzpyrene per kilogram of soot. Polycyclic aromatic hydrocarbons including 3 : 4-benzpyrene have also been detected in the exhausts of internal combustion and diesel engines. Again, Kotin, Falk and Thomas, in Los Angeles, have obtained tumours on mouse skin with artificially produced smog free from aromatic hydrocarbons. There is some evidence that the responsible agents here are epoxides arising from oxidation of hydrocarbons in petrol vapour.

There is little doubt that specific chemical substances are also responsible for the increased liability to lung cancer found among workers in a number of industrial processes. The classical example of this, among the miners of Schneeberg, in Saxony, and of Joachimsthal, in Bohemia, is almost certainly due to ionizing radiations from radioactive gases and/or dusts. Other examples, in the nickel, chromate and asbestos industries and among the hæmatite miners of Cumberland, seem to be associated with dusts of metals or metallic oxides or salts. The total number of cases attributable to these occupational causes may be very large, and Hueper, in fact, regards such causes as outweighing cigarette smoking in importance.

Clearly, the whole question of lung cancer and its increase is complex and is unlikely to admit of a simple solution. The balance of evidence is strongly in favour of the view that carcinogenic chemical agents are primarily concerned, although in the present state of our knowledge, it is very difficult to arrange the sources of these in any undoubted order of importance.

ORDOVICIAN VOLCANOES

THE presidential address by Dr. G. H. Mitchell to Section C (Geology) recalls the centenary this year of the birth of a great Irishman, John Joly, to whose brilliant thought modern ideas of vulcanicity and earth-movement owe so much. Joly suggested that a direct connexion exists between heat accumulated within the crust of the Earth as a result of radioactivity and the periods of orogenesis and volcanic outbursts which recur from time to time.

Despite the vicissitudes of many millions of years of geological history, there appear even now among the outcrops of Ordovician strata at the surface in the British Isles a remarkable number of volcanic rocks which afford evidence of one of those outbursts of volcanism. They form, as it were, a great broken ring, near the centre of which lies the city of Dublin. In Ireland the most important exposures are in Tyrone, Galway, Waterford and Wexford. Across the Irish Sea, the Welsh Ordovician rocks, stretching from St. David's to the Menai Straits, include numerous lava-flows and pyroclastic rocks. Farther north, the products of great volcanoes form most of the high fells of the English Lake District. Other remnants of the eruptions of those far-off days are found across the Scottish border in Ayrshire, as scattered outcrops throughout the Southern Uplands of Scotland and even as far afield as Arran, Aberfoyle and Stonehaven. We do not know how many more such deposits lie buried beneath later rocks or have been removed by erosion during the many periods of denudation which have occurred within the 350–400 million years that have elapsed since they were erupted.

The composition of the lavas varies from andesites to rhyolites, with notable developments of spilites. The pyroclastic rocks range from agglomerates to the finest dusts, and include lithic, crystal, vitric and welded tuffs, comparable in composition to the lavas with which they are associated. Both lavas and tuffs show considerable alteration, with the formation of many secondary minerals.

Ordovician volcanic activity broke out early in Arenig times at a number of centres in Ireland, Wales and Scotland. So far as the imperfection of the geological record will allow, the violence of the eruptions appears to have increased with the opening of new foci in the Llanvirn Epoch, in particular in the English Lake District. There is evidence that this phase was followed by uplift and considerable erosion, which are revealed by striking unconformity, pre-Caradoc in age.

Volcanic activity flared up again in Caradoc times. To judge by the thickness of the surviving deposits, there must have been centres of importance in Ireland and North Wales, but in England and Scotland the outpourings were on a smaller scale. With the passing of the Caradoc Epoch volcanism waned, and in the Ashgill Beds, formed at the close of the Ordovician Period, there only remain thin beds of tuff or lava to mark the dying phases of one of the most violent of those volcanic storms which on several occasions have swept the area where the British Isles now stand.

EVOLUTION OF ORGANIZATION IN THE NERVOUS SYSTEM

PROF. J. Z. YOUNG points out in his presidential address to Section D (Zoology) that the controlling functions of the nervous system are a special development of the systems by which all life is regulated. The properties of signalling, memory and prediction that we attribute to the nervous system can also be recognized throughout cellular activity. In order to describe complicated self-adapting systems such as living organisms, we have to consider that there is a sense in which the system 'could' do several things and that it 'selects' the appropriate ones in the light of past history. The behaviour of such complicated aggregates can only be adequately described if we know their history over considerable periods. One method for handling such a study is to use the analogy of signalling and language, where the function of a symbol is to influence the choice among the various things that a human being can do. The significance of the word in this respect is not seen from the wave-form of its sound unless the student has a complete history of the way this wave-form has influenced human populations in the past.

For the control system of an organism to be able to maintain stability it must contain what we may call a coded representation of those events in the outside world that are likely to be significant for its life. We are familiar with this concept when considering the storage of memories within the nervous system, but it is equally applicable to the control systems of cells. The replication of a representation without distortion through a series of copies requires that it shall consist of discrete units. The molecular aggregates within cells can be considered as such specific unit signals, not only within the nucleus but probably also in the cytoplasm.

Signalling between cells presumably developed out of the system of signals within cells. As nervous systems became more complicated they allowed selection of responses from larger sets of possible actions. Moreover, the actions are influenced by memories of sets of occurrences in the past. In *Octopus*, memories can readily be set up ensuring that one figure will be attacked and another avoided. If the amount of tissue available is reduced by removal of part or all of the vertical lobes, there is a corresponding reduction in the accuracy with which the animal forecasts the probable outcome of a situation. The nervous tissues responsible for the storage of the memories consist of a set of lobes each connected with the next through a plexiform arrangement and containing numerous small cells. The lobes can re-excite each other in a circuit. The specific representations that ensure correct responses presumably consist of facilitated pathways in these networks. During the period after an octopus has received food, the probability that it will attack any moving figure is increased, and conversely after a shock. These effects still occur after removal of the vertical lobes, but both last for a shorter time than in the normal animal. In the absence of these lobes, octopuses can learn only if trials are given at short intervals. Moreover, memories set up before operation are disturbed but not wholly lost after removal.

Although we are still ignorant of the nature of these memory processes, we can see that they involve selection among many possible alternative pathways, such as are open to a system composed of aggregates of dissimilar entities. Such systems can show the process of 'adaptation' with various time-scales, either by selection of certain responses during the life-time of the individual or by the slower process of 'natural selection'. In general, animals with large brains that learn well live longer, reach a larger size and breed less rapidly than those which depend mainly on natural selection to ensure that their responses are adequate. All these problems can be considered together. We can inquire how each species receives the information that ensures that its control system contains a representation that elicits responses which ensure survival. The analogy of information theory is helpful at least for introducing us to the nature of the problems to be solved.

THE EVERLASTING HILLS

"MOUNTAINS are not everlasting, nor are they by any means all of the same age. The antiquity of the Alps and the Himalayas is little compared to that of our Scottish and Welsh mountains, which indeed are so low because they are so old." This view, expressed by Lord Avebury in 1902, is quoted by Prof. David L. Linton in his presidential address to Section E (Geography), who points out that it is quite in line with that of Sir Archibald Geikie, who thought the "prodigious denudation" involved in cutting the glens of the Scottish Highlands could be ascribed to Tertiary times, but relegated the fashioning of the "plane of marine denudation" represented by the present Highland summits to the Palæozoic.

In the half century that has since elapsed, it has become clear that mountains can be carved from uplifted segments of the Earth's crust in much less time than such workers supposed. Thus the Kaikoura Ranges of New Zealand, some 9,000 ft. high, have been carved from the solid in Pliocene and later times. The mountains of Scotland erected by the Caledonian orogeny were laid open to their granite cores, and possibly peneplaned, before the Middle Old Red Sandstone was deposited. The Hercynian mountains of Devon which were rising in Lower Coal Measure times had been largely destroyed by early (and completely peneplaned by late) Permian times. From such evidence, combined with the absolute chronology provided by radioactive dating, it becomes clear that high mountains on continental margins are likely to be base-levelled in 20–40 million years; and since post-Cretaceous time is reckoned to comprise some 70 million years; it is evidently more than ample for two erosion cycles to have been completed in Britain, on hard and soft rocks alike. It is clear also that our existing hill and mountain scenery will display no pre-Tertiary elements unless these have been exhumed during Tertiary time.

Geomorphologists in Britain and Ireland are to-day attempting to educe from the forms of our hills the pattern of their physiographic history. In the mountains of most drastic glacial sculpture, which can be shown to be essentially those that to-day receive more than 100 in. precipitation a year, little if anything survives that can be called pre-glacial. Elsewhere, and especially in the massive uplands of eastern and southern Scotland, central Wales and south-east Ireland, the uplands have been only lightly modified by the ice and enough survives from later Tertiary times to make attempts to construct a denudation chronology both possible and profitable. Such attempts are still in the exploratory stage and indeed it appears that some of the work done in the past twenty years has pursued a false scent and led to conclusions for some areas that are inherently improbable. This set-back, however, need not daunt us, and if care is taken to see that all the possibly relevant evidence is used, and to avoid over-dependence on a single set of morphological criteria, there is no reason why the familiar forms and features of the hills of our homeland should not in time disclose their ages to within two or three millions of years.

THE BALANCE-OF-PAYMENTS PROBLEMS OF A EUROPEAN FREE-TRADE AREA

IS it possible in Western Europe to combine free trade with the maintenance of full employment and the avoidance of deficits on international balances of payments? Prof. J. E. Meade, of the London School of Economics and Political Science, states in his presidential address to Section F (Economics) that there are five possible approaches to an answer to this question; they may be called the liquidity approach, the gold-standard approach, the integration approach, the direct-control approach, and the exchange-rate approach.

(1) The *liquidity approach* relies upon increasing the international monetary reserves of the deficit countries. This will not remove a permanent balance-of-payments disequilibrium. But the surplus countries of Europe might provide temporary finance to the deficit countries of Europe to tide over the time during which more basic remedial measures were having their effect. The European Payments Union is not well designed for this purpose; but a European Monetary Fund might be used in its place.

(2) The *gold-standard approach* means that a country with a surplus on its balance of payments (like Germany) must inflate, and a deficit country (like France) must deflate, its domestic prices and incomes until the balance-of-payments disequilibrium is removed. Surplus countries certainly have an international obligation to avoid domestic deflations and deficit countries to avoid domestic inflations. But it is dangerous to rely solely on this method, because it would necessarily mean the abandonment of domestic monetary and budgetary policies for full employment and for domestic stabilization by the national governments of Europe.

(3) The *integration approach* involves a sufficiently extensive unification of European financial policies and institutions so that payments between two European countries, such as Germany and France, present no more difficulty than payments between two regions of one country, such as England and Wales within the United Kingdom. This, however, involves a European government with powers to institute a common currency and central bank, to carry out a single European budgetary policy, to determine a single European commercial and exchange-rate policy *vis-à-vis* third countries and to carry out an effective development policy for depressed regions in Europe.

(4) The *direct-control approach* implies that a deficit country should be free to restrict imports from other countries. If it restricts imports from its partners, this is, of course, a direct contradiction of the idea of a free-trade area. A European deficit country may be able to do something by restricting imports from third countries without restricting imports from its European partners; but in the circumstances of Europe, not too much reliance can be placed on this possibility.

(5) There remains the *exchange-rate approach*, which means that the foreign-exchange value of the currencies of the surplus countries should be raised and of the deficit countries should be lowered.

An effective solution of the balance-of-payments problems of a European free-trade area rests upon a combination of elements from all these five methods. Exchange-rate variations will certainly have to play a larger part than they have in the immediate past. In particular, some appreciable revaluation of the German mark and devaluation of the French franc are essential.

EDUCATION AND TRAINING FOR THE ENGINEERING INDUSTRY

SIR DAVID ANDERSON, director of the Royal College of Science and Technology, Glasgow, takes "Education and Training for the Engineering Industry" as the subject of his presidential address to Section G (Engineering).

Table 1. OUTPUT OF PROFESSIONAL ENGINEERS

The figures for first degrees and diplomas are those given in the University Grants Committee returns under "Technology"; the great majority of these will be engineers. The London figures all relate to engineering. The Higher National Diplomas are in mechanical and electrical engineering, and the Higher National Certificates are in mechanical, electrical, civil and production engineering. It has been assumed that 50 per cent of those getting Higher National Certificates are of potential professional standard

Qualification	Session 1950–51	1951–52	1952–53	1953–54	1954–55	1955–56
First degrees and diplomas (University Grants Committee returns)	3,175	3,145	2,999	3,009	2,760	2,871
London, internal degrees from institutions with recognized teachers	242	268	231	209	219	233
London external degrees	570	456	469	309	250	237
Higher National Diplomas	245	203	264	239	251	310
Higher National Certificates, 50 per cent of output	2,598	2,687	2,769	2,860	3,041	3,107
Total	6,830	6,759	6,732	6,626	6,521	6,758

Engineering is the most widespread and basic of our manufacturing industries. Not only is it a major industry in its own right but also nearly every other industry depends on engineering for the design, operation and maintenance of its plant and equipment. The output of engineers in Britain lags far behind our requirements. Every scientific discovery opens up a fan of potential applications, but as Table 1 shows, our output of engineers remains relatively static, and, as a result, many promising developments have to be put in cold storage.

It is difficult to say anything new about education and training for the engineering industry, but the efficiency of the industry is so intimately dependent on the quality of both that periodic reviews are justified.

A problem common to all technological courses is the place which should be given to 'liberal studies'. The magnitude of the problem can easily be exaggerated, but there is general agreement that they should have a place. The difficulty usually alleged that there is no time could be overcome by taking some half-hours from the many laboratory periods, and devoting them to non-technical subjects. As regards the use to which the periods might be put, everyone will have his own ideas, and rightly so. There can be a wide range of choice.

Universities and technical colleges, especially technical colleges, are frequently blamed for failing to teach their students how to think; but this criticism is often unfair. On the whole, the quality of teaching is good; the trouble is that good thinkers are rare. Nevertheless, the problem should not be glossed over, and, with the allied problem of over-crowded syllabuses, it might very well be the subject of some 'work study' research by university departments of education and the proposed staff college for teachers, if and when it is set up. For one thing, more departmental co-ordination is needed. No manufacturing firm could run with as little departmental co-ordination as takes place in the average university.

Increasing attention is being paid to management studies in engineering courses. Without good management, the maximum return cannot be reaped from technological advances. An ideal arrangement would be a planned series of short residential courses spaced throughout the earlier years of a man's professional life.

A higher standard of technology needs to be backed up with better technicians and craftsmen, and British industry should make a serious examination of its apprenticeship system. At the start of the century, apprenticeship was much the same in Continental countries as in Britain; to-day British and Continental practices are widely divergent. In West Germany apprenticeship is controlled on a national basis, with compulsory attendance at a vocational school, and an apprentice must pass a written, oral and practical examination before he can be certified as a skilled craftsman. The scale on which apprentice training is conducted can be seen from figures for the city of Frankfort (population about 600,000), where, in a recent year, 4,800 candidates were examined in 126 different trades. In France an apprenticeship may be served not only in industry but also in an apprentice training centre. There are nearly a thousand such centres catering for 160,000 apprentices. In the light of what is happening abroad, it is disturbing to reflect that, in Britain, a youth can still become a skilled craftsman without having attended a single class or passed a single examination in the whole five years of his apprenticeship—and many do: 'serving time' is the only compulsory requirement.

In the United States people move freely in both directions between industry and teaching. In Britain we are far more static, and one reason is the lack of interchangeability in our superannuation schemes. University teachers are on one scheme, technical college teachers on another, and in industry each firm has its own. A person cannot, as a rule, move from one to the other without incurring some kind of superannuation penalty. What is needed is superannuation interchangeability between universities, technical colleges and industry. This would encourage freer movement of staff, which would be of all-round benefit.

In these days of rapid technological advance, teaching staffs should return to industry to be brought up to date in industrial practice, but how rarely this happens. In the Willis Jackson Report on "The Supply and Training of Teachers for Technical Colleges" figures are given showing that, in 1956, only 34 out of 11,500 teachers in technical colleges returned to industry for periods which might be as little as a few weeks or even days.

The engineering industry should establish many more research fellowships. There are too few opportunities for the pursuit of research beyond the Ph.D. stage, which, after all, is not much more than a training in research methods. The number of such research fellowships in Britain in relation to the size of the country's industrial budget is pitifully small.

ARCHÆOLOGY AS SCIENCE: PURPOSES AND PITFALLS

PROF. C. F. C. HAWKES, in his presidential address to Section H (Anthropology and Archæology) considers the question of what sort of science archæology, which has grown out of the physical sciences of geology and palæontology on one hand and the social sciences of history and ethnology on the other, should be. Prehistoric archæology is often regarded as the purest and best because it is the most scientific, that is, it is based solely on the enumeration and classification of material remains, the study of which involves collaboration with natural scientists. Team-work between archæologists and natural scientists is the biggest single factor now operating, at least in the prehistoric field, to improve the quality and extend the range of archæological research. But the theme of Prof. Hawkes's address is not archæology and science, but archæology as science, and he believes more thought should be given to purposes in archæology and to the possibility of pitfalls ahead. The principles behind archæological work are really only two: first, that people in the past did things for purposes which in most cases can be understood; and secondly, that where different people did the same or similar things and connexion is possible between them, there should be single explanations to cover both or all of them. In so far as these principles are put into practice, archæology may be called scientific: the pitfalls lie in neglecting them.

The prehistoric wing of archæology, having its roots in geology and palæontology as evolutionary natural history, studies man in his place in the biome and his gradual development of the techniques and social organizations to enable him to control his environment. Such primary prehistory is indispensable. The study of the Palæolithic and Mesolithic is essentially world-wide, and primary prehistory continues through the transition from hunter–fisher life to the study of communities that grew vegetable and animal food and developed the stable social groups which are the essential feature of the Neolithic. This study has an essential place among the intellectual possessions which make the modern outlook upon the work differ from any previously attained. The distinctively scientific characters of primary prehistory are that it excavates sites according to the principles of stratigraphy borrowed from geology, it makes exact measurements and comparisons in the classification of finds, and collaborates with the natural scientist in the analysis of anything that will aid archæological interpretation.

Progress in the study of the Palæolithic is satisfactory. Evidence about the economics of Upper Palæolithic hunting life is not wanting; the size of the social group can be estimated in terms of hunting strength and winter house size, and it is possible to follow the seasonal movements following game. Upper Palæolithic art can be interpreted in terms of hunting-magic, and in it are revealed the germs of a religion of animal and human fertility. Much the same is true of the hunting and fishing communities of the Mesolithic. The diffusion of a new mode of subsistence by farming in the Neolithic, and movement across the continents, which in the Palæolithic and Mesolithic are to be explained almost entirely by climatic factors, can in the Neolithic be understood as a search for new land reinforced by the pressure of the growth in population. All this is intelligible to reasoning based wholly on material and environmental factors.

However, European prehistory in the second as well as in the first millennium B.C. cannot justifiably be treated as altogether primary. There is nothing demonstrably climatic nor arguable from the food quest to explain the diffusion of Bell-beakers and their associations over so much of Europe in the second millennium. What explains the proliferation and diffusion from the south Russian steppe and the east European plain of people burying their dead under round barrows, singly, and with stone shaft-hole axes and pottery embellished with cord-impressions? Here explanation has to pass beyond the primary level of reasoning if it is to remain scientific and adhere to the evidence. In the first half of the second millennium B.C., Indo-European languages were being spoken in Anatolia and Greece. Early Greek is revealed in the Linear *B* Minoan and Mycenæan tablets, and its evidence can be used in conjunction with later Greek evidence, and with reasoning on the lines of comparative philology, to augment the conclusions philologists have already drawn on the antiquity of social and religious institutions common to all the speakers of languages of that Indo-European family.

Wherever archæological studies approach evidence bearing on language or upon institutions known from texts, that is, wherever cultures are found not directly explicable by the economic basis of subsistence, it is necessary to transcend prehistory in the primary mode, and to collaborate with the philologist and historian. This way, too, lies the needful reconciliation between archæology and ethnographic and social anthropology, which require societies to be apprehended as functional wholes. Archæologists must welcome all trustworthy evidence, whether from scientific or from humanistic sources, which will illumine the transition from prehistory to history. The trouble with archæology is that alone it can reveal so little that is non-material.

The claim that archæology should be regarded as a science is bound up with its ability to compare and classify finds and to construct systems on that basis. To-day the periodical literature is so great that it is becoming less and less easy to find published comparisons. The basic information of the natural sciences and of humanistic scholarship is gathered into works of reference. But with rare exceptions archæological books are all introductory or popular. Prof. Hawkes calls for a corpus treatment of all archæological antiquities on uniform lines, not in books but on cards. The "Inventaria Archaeologica" is meant to cover a selection only. It ought to be backed up by card-corpuses which, Prof. Hawkes suggests, might be prepared in a period of five years, for Neolithic, Bronze and Iron Age Britain and Ireland, at a cost of some £10,000. Central institutions in capital cities would be required to keep the corpus annually up to date. Thus the material facts of archæology would be accessible to all and only then, not by faith alone but by works also, could archæology fully substantiate its claim to be a science.

CHEMICAL TRANSMISSION AT NERVE ENDINGS

TRANSMISSION may be defined as the communication of activity from one cell to a second, anatomically separate cell; synaptic transmission occurs where both are nerve cells; neuro-effector transmission where the second is an effector cell. The presidential address given by Sir Lindor Brown to Section I (Physiology and Biochemistry) is limited mainly to neuro-effector transmission. The predominating effector is the skeletal musculature; other important effectors are smooth muscle and gland cells. Both nerve and effector cells constitute closed systems in which, at rest, the inside is 50–90 V. negative to the outside. Both have the property of excitability and the ability to conduct self-propagating waves of electrical activity brought about by a sudden change in the properties of the limiting membrane which permits local electric currents to flow, and excite similar changes in the adjacent membrane. Transmission from one cell to another involves more than this electrical spread. Specific substances are discharged at the nerve endings which excite or depress the next cell.

At the skeletal muscle junction and ganglionic synapse, the chemical transmitter is acetylcholine. In the nerve endings at the motor end-plate there is a large number of units, capable of liberating a small charge of acetylcholine. Individual units are continuously discharging in a random fashion, but the amounts are insufficient to excite. With the arrival of a nerve impulse a hundred or more units discharge synchronously, the acetylcholine released reacts with receptors in the muscle fibre, short-circuits the end-plate membrane; and local electrical currents sufficient to depolarize the adjacent membrane and to initiate a propagated wave of depolarization, are produced. The combination of acetylcholine and receptor is rapid and is limited by the destruction of the transmitter by the enzyme cholinesterase, concentrated at the end-plate. It has even been suggested that this enzyme is the receptor.

Information on synaptic transmission is scantier largely because of the difficulty in recording electrically from the inside of a ganglion cell. The longer duration of transmitter action and the less obvious effect of anticholinesterases suggests that diffusion rather than destruction may be responsible for the removal of the transmitter.

Post-ganglionic neurones of the involuntary nervous system may liberate either acetylcholine or noradrenaline. On the heart, cholinergic (vagal) fibres depress, whereas adrenergic fibres excite. This depression of cardiac muscle by acetylcholine might suggest that its mode of action differs radically from that at the motor end-plate. Recent work suggests a fundamental similarity. At the motor end-plate the membrane permeability to all ions is increased, so that depolarization and excitation result. In the heart, the increase is restricted to the potassium ions and possibly the chloride ions, with a resulting hyperpolarization and reduced excitability. The mode of action of adrenaline and adrenergic nerves on the heart is still obscure.

Information on the action of the chemical transmitters on smooth muscle is also limited because of the difficulty in recording electrically from inside the cell. It appears, however, that where acetylcholine excites, as in the intestine, it also reduces the membrane potential, and that adrenaline, which inhibits, increases the membrane potential.

Although the nerve impulse is 'all or nothing', the amount of transmitter liberated is almost certainly variable. At the muscle end-plate previous moderate activity can increase the number of units released, whereas excessive activity can lead to a decline sufficient to produce, in amphibian muscle, complete neuromuscular block. However, under normal conditions, similar exhaustion of the terminal stores of transmitter is unlikely in post-ganglionic neurones because of the low frequency of natural discharge.

Accumulation at, and diffusion from, the site of liberation of acetylcholine with consequent extension of its action is unlikely. The presence of 'true' cholinesterase at the site of liberation and non-specific cholinesterase in the blood and tissues offers a double barrier to such extension.

Without eserine to protect acetylcholine from enzymatic destruction, little would be known of cholinergic transmission; what little is known about adrenergic transmission has been gleaned without the use of a specific inhibitor of any inactivating enzyme. Mono-amine oxidase has been suggested as playing a part comparable to cholinesterase. There is much evidence to support this, but recent work attributes inactivation to combination with the tissue receptors. Whatever the mechanism, it is easily swamped; so that accumulation of noradrenaline, local extension of its action by diffusion, and escape into the blood stream can all occur. As a consequence, localization of action comparable with acetylcholine-mediated effects is improbable.

THE WORKER AND HIS WORK

IN his presidential address to Section J (Psychology) Dr. H. G. Maule points out that at the beginning of the nineteenth century, as industrialization proceeded with great rapidity, there was but little attention paid to the personal and human needs of the industrial worker. In general, industrialists were concerned more with the new, developing, techniques of engineering and with new machinery than they were with people. There were, however, individual examples of firms which appreciated that workers as much as machines required attention. Against this background a developing public conscience gradually intervened, and laws were passed which helped to make the workers' lot more tolerable. Leonard Horner, one of the original inspectors of factories, reported some interesting and successful experiments in which hours of work in the cotton industry were reduced, with advantage not only to production but also to the general well-being of the worker. He admitted that he had not realized that shorter hours of work could lead to more punctual attendance, the avoidance of waste, and the general raising of industrial morale and so increase industrial efficiency.

Towards the end of the century a carefully conducted experiment on the effect of reduced hours was carried out in a Lancashire engineering works, and the result confirmed these findings of the earlier pioneers. Speaking of this experiment, Sir William Mather said that in his view the most economic production was obtained only so long as workers were at their best, and no economy was effected by continuing beyond this point. Up to 1914, however, it was only in respect of hours of work that there was any serious thought about the relationship between the worker, his work, and his working efficiency. In 1914, faced with war demands, industry attempted to solve its production problems by extending hours of work with little or no limit. So unsuccessful was this policy that a special committee to investigate the health and efficiency of munition workers was set up in 1915. When this committee was disbanded, it was succeeded by a peace-time organization, the Industrial Fatigue Research Board, which for the next thirty years carried out research and published its findings. In this way the foundations for modern industrial psychology were securely laid. At that time the main problems were those of working environment and methods of work. Even so, the early investigators directed attention to many of those aspects of people at work which are to-day regarded as the most important.

Between the two World Wars the emphasis changed. Studies carried out in the United States stressed the great significance of psychological forces operating within the working group and demonstrated the adverse effect on both well-being and production which might result from failure to pay adequate attention to these psychological forces.

By the time of the Second World War a substantial body of knowledge had been accumulated about conditions most favourable to efficient performance. But even so, many managers of industry were ignorant of the knowledge that was available to them.

The war years saw psychology playing its main part in application to the problems of the Armed Forces, particularly in the development of personnel selection. In this field striking contributions were made to the more effective use of Service personnel.

Since the end of the War there have been further important developments in the application of psychological principles to industrial problems, though there is still a considerable gap between knowledge and its application. We know, for example, that industrial neurosis accounts for the loss of some seventy million working days each year. It has been suggested that £700,000,000 a year is lost through people changing from job to job. We know some, but not all, of the factors influencing psychological mal-adjustment; we are beginning to understand the significance of the attitude of the worker not only to his work but also to those with whom he works. Design of equipment and machinery is now being recognized as having a psychological as well as engineering implication. A beginning has thus been made in our knowledge of the psychological needs of people at work.

Industry should recognize that sociology and psychology can make a contribution towards solving the problems of industrial management.

ASPECTS AND PROBLEMS OF CONIFER EMBRYOLOGY

PROF. J. DOYLE remarks in his presidential address to Section K (Botany) that our understanding of the nature of conifer embryology has been somewhat hampered by the fact that early work was centred on north temperate forms with special emphasis on the Scots pine. As a result, some presentations seem to make the matter a little obscure, whereas in reality it is relatively simple. The various embryogenies in the conifers can be largely resolved into a number of obvious modifications of a basal plan, with only a few cases which present any difficulty in fitting into the scheme.

The nature of what appears to be the basal plan can be most readily appreciated from a consideration of embryogeny in the podocarps. After fertilization, the diploid fusion nucleus undergoes a number of free mitoses, up to five, to give at the archegonium base a number of free nuclei, up to 32. At membrane formation these are arranged in a single upper tier of unclosed cells, the 'open' tier, and a lower group of primary embryo cells. An internal division, affecting all the nuclei, follows. Divisions in the 'open' tier are orientated along the axis of the pro-embryo and thus give rise to an uppermost single tier of cells, the upper or *U* tier, and, just below it, the next single tier of cells, the suspensor tier, *S*. The primary embryo nuclei are also duplicated. The nature of the mature pro-embryo can be expressed as a formula, $U : S : E$, to which can be added in any given case the number of cells in the parts so developed. The *U* tier is most often ephemeral. The *S* tier elongates to give the primary suspensor.

Excluding the araucarians, this plan is found in all the conifer families. In the Pinaceae, however, the *S* tier does not elongate. This is the so-called 'rosette' tier of *Pinus*. The proximal layer of the *E* cells elongates to function as a substitute suspensor. *Pinus* embryogeny, in detail, is not typical of conifers.

The varying embryogenies in the families and genera can readily be related to a limited number of general evolutionary trends the expression of which seems to be, most often, in no way related to systematic affinities. This phenomenon, the expression of tendencies without apparent regard to systematic affinity, is a dominating feature in conifer embryology both in the pro-embryonic and gametophytic phases. As extreme examples there may be cited: the occurrence of four-celled pro-embryos in forms as distinct as *Athrotaxis*, *Callitris*, and *Torreya*; the appearance of similar types of cleavage polyembryony in *Taxodium*, *Keteleeria* and *Podocarpus*; or the hyphal-like pollen tube in *Tsuga*, *Saxe-Gothaea* and *Araucaria*. Embryological data, therefore, can be applied only with great discretion, if at all, to questions of affinity in conifers. If, however, the embryological data be considered in themselves, it is now possible to indicate, at least along general lines, the main evolutionary trends which have resulted in modifications in the basal plan.

Evolution in the conifers thus appears to be related to two groups of evolutionary trends: one group related to systematic divergence and diversification, the other to modifications in embryological stages. These two groups appear to be separate, as it were overlapping, and the nature of their connexion, which must be intimate, remains a problem. Selection does not seem to be a factor affecting the embryological trends.

THE EDUCATION OF THE COUNTRYMAN

IN his presidential address to Section L (Education), Mr. L. R. Missen defines the countrymen he has in mind as the two to two and a half millions in Britain who live in the open countryside outside villages and probably three and a half to four millions who live in villages. He deals with two misconceptions which are still held by the urban population: that the countryman is the mental inferior of the townsman; and that all those who live in the country work on the land. These misconceptions have in some degree affected the recruitment of teachers to rural schools. The evidence which he quotes shows that with regard to the former the case is at least 'not proven', and there is no difficulty in showing a wide variety of occupations in most rural areas. The theory that country children are mentally inferior to town children is examined, and the evidence of Sir Godfrey Thompson and others is brought to show that this is a false idea. On the other hand, there are distinct differences between rural children and town children. It is claimed that whereas the country child is frequently slower than his counterpart in the town to grasp a new idea and to assimilate facts, he is more thorough and more painstaking. The country child may lack the fluency of the urban child, but fundamentally his mental equipment is just as good.

The rural school child has been handicapped in the past in many instances through education in schools which were too small, although small schools have some advantages over larger ones. The single-teacher school is rapidly disappearing and the two-teacher school will be the smallest.

In the life of the countryside the most remarkable change is coming about through the mechanization of agriculture, and there is now a pressing demand for men and boys with a sound knowledge of the elementary principles of science. At the school-level, the most exciting development is the new secondary modern school, which is providing an increasing number of well-trained and competent men and women. The rural grammar school will continue to make a valuable contribution in the countryside.

The methods of agriculture, now increasingly scientific, are being met in several ways. The National Agricultural Advisory Service and the farm institutes have done much to increase the farmer's and the farm worker's understanding of their craft; evening classes of the local education authority and day-release classes have supplemented this work. The countryman is in some ways more fortunate than the town dweller in his choice of leisure time occupations; he is less likely to spend his spare time being entertained at the cinema or at football matches. He is a good reader, and the evening institutes offer him a wide variety of cultural and recreational activities.

Mr. Missen concludes that the countryman has been less impressed by the glamour of the twentieth century, and that the steady and unalterable succession of the seasons will maintain a slower tempo of life, which must have nationally a balancing effect. The countryman has far more time for consideration of life's problems than the townsman.

THE ROLE OF AGRICULTURE IN THE BRITISH ECONOMY

SIR JAMES TURNER, president of the National Farmers' Union of England and Wales, is presiding over Section M (Agriculture), and the theme of his presidential address is "a full measure of technical progress in the future will depend very much upon the agricultural industry being able to count upon the right basis of political and economic conditions".

After referring to the long-term planning that is necessary in agricultural production, Sir James discusses the advantages resulting from a stable industry: "The gain to producers from stable markets is fairly obvious. To consumers and tax-payers, the benefits are complementary, accruing from the avoidance either of sharp changes in the cost of living with their consequent impact on wages and production costs or of sudden variation in Exchequer liability".

Sir James stresses that the industry's ability to lower unit costs depends not solely upon its own efforts but also upon two extraneous factors. The first of these is ability of the Government to halt inflation; and the second is the efficiency of those industries which supply agriculture with goods and services—for these are valued at the present time at some £800 million a year.

The challenge is to find new and better ways of putting the productive resources of agriculture to the most economic use. First of all, there is no doubt that grass, the United Kingdom's largest and most important crop, offers great scope for rapid development in yield, utilization and conservation.

Work-study can make many contributions to agricultural efficiency. The stage has now been reached when work-study knowledge and advice should be made available to farmers on a basis similar to that of the National Agricultural Advisory Service, and he thinks that every district officer of the Advisory Service should receive training in work-study.

A new interest in farm building design among architects, builders and industrial designers is also needed. That is why the National Farmers' Union of England and Wales has recently established a research fellowship in the design of farm buildings, which is to be administered by the Nuffield Foundation.

On the question of efficiency, Sir James thinks it a pity that whereas farmers are always under pressure on the score of efficiency, very little is said about the efficiency of the ancillary industries. They have the benefit of a firmly based home market, and they should share with the farmers the obligation to cut at least their operational costs to the minimum and so allow the consumer, through the medium of the farmer, to share in that benefit.

As regards the achievements of the producer-marketing movement in Britain, there is no doubt that it ranks, with the guarantee system, as one of the two most revolutionary agricultural developments of our generation. On the distributive side it is in the sphere of presentation, pre-packaging and self-service distribution of branded British foodstuffs, effectively advertised, and carrying a continuing guarantee of quality, that early and dramatic advances can be achieved.

Summing up, Sir James believes that what we really need is a combined operation in the economic, financial, technical and scientific fields if we are to succeed in transforming the structural basis of the industry during the next generation, on a scale comparable to the agrarian revolution of the eighteenth century. With a stable support structure, and a proper flow of credit, there will be unlimited scope for the application of new knowledge.

THE VASCULUM AND THE MICROTOME

IN his presidential address to Section X (Assembly of Corresponding Societies), Prof. D. A. Webb discusses, under the title of "The Vasculum and the Microtome", some of the problems in the relationship between laboratory biology and natural history to-day. The contrast between them to some extent coincides with the contrast between the interests of the amateur and of the professional, but the two distinctions are not quite the same; for although the amateur laboratory worker has unfortunately become almost extinct on account of the increasing complexity and cost of apparatus, there are a number of professional biologists who are primarily field-workers. These men are in an especially favourable position for bridging the gap between amateur and professional and for encouraging each to help the other.

The welcome revival of interest in natural history among professional biologists in the past twenty years, and the many examples of fruitful collaboration that have been seen in this period between amateur and professional and between laboratory worker and field-man, must not blind us to the fact that there is a necessary tension between the two approaches, and that unless each side is able to show tolerance, and respect for interests that it does not share, this tension will find expression in hostility and polemics. Most biologists belong to one or other of two contrasted types, which differ from each other in their primary interest in the subject, and consequently in their method of approach and their sense of what is important and what trivial. One is attracted primarily by the richness and diversity of Nature; he seeks for classifications, principles and laws to help him to explore this diversity effectively and to comprehend it in his mind; but its complexity is for him a primary datum which no theorizing can reduce to simplicity. Such a man is naturally a field-worker. To the other type this complexity and diversity is, if anything, an irritant; he is interested in analysis, abstraction and simplification; he seeks above all for the understanding of the processes of life and of the principles of homogeneity that underlie the diversity. For these ends the laboratory is more effective than the field.

Neither of these attitudes can, if pressed to its logical conclusion and pursued to the exclusion of the other, get very far towards the understanding of the organic world. The complexity of this world is so great that without analysis and simplification we can but contemplate it, wrapped in a fascination that may be pleasurable but scarcely scientific. On the other hand, it must be realized that the organism lives every moment of its life not in the cold serene world of genetic ratios, enzyme equilibria and the thermodynamics of infinitely dilute solutions, but in a grosser, pullulating, phenotypic world, characterized by a complexity of which only a minute fraction is reducible by our laws and theories.

The impact of cytogenetics on taxonomy serves to exemplify both the profit to be gained by close collaboration between the laboratory and the field-worker, and also the dangers of misunderstanding between them. Partly because of the lack of suitable semi-popular expositions of the lessons that traditional taxonomy must learn from cytogenetics, many amateurs are still impatient and distrustful of the subject, and do not realize how often it gives them a clue to unravel a confused situation, or an objective instead of a speculative basis for their conclusions. On the other hand, some cytogeneticists, notably Prof. C. D. Darlington in his "Chromosome Botany", are so impressed with the importance of their own studies that they represent them as the only road to biological truth, and with a fine disregard for logic hold up to contumely the principles of a taxonomy the categories of which they are using every day.

But in spite of some arrogance on one side and ignorance on the other, a great deal of effective co-operation has been achieved. It is only the rare mind that can at once retain in view the complex pattern of Nature and achieve the abstraction necessary for its analysis; but on such minds we are dependent for any real advance in our understanding of organisms. The rest of us can, however, at least avoid putting obstacles in their path; and in bringing our brick to be built into the structure of scientific knowledge we must realize that our neighbour's brick, though it differs in shape and colour, may be just as useful as our own.

THE REPUBLIC OF IRELAND

A View of Ireland

Edited by James Meenan and David A. Webb. Pp. xvi+254+17 plates. (Dublin: Local Executive Committee of the British Association for the Advancement of Science, 1957.)

THIS Handbook, published especially for members of the British Association by the Local Executive Committee in Dublin, maintains the high standard, especially in sumptuousness of production, which has recently been attained by previous local committees at other meeting centres.

As would be expected, this work concentrates, in twelve chapters, mainly on the geography and geology, biology, agriculture, archæology and folklore, and economics of the Republic of Ireland. One chapter deals with the Irish language, and the final chapter is concerned with interesting details about Dublin itself, including its main scientific institutions. In a folder attached to the back cover is a simple map of Ireland indicating the counties and the main towns. The indication of the border separating the six counties comprising Northern Ireland is by no means distinct enough. Many visitors will wish to know which are the six counties, but few will recognize the border on this map. The fact is that the border is there, and should be clear on such a map. A second map will prove more useful since it gives details of Dublin and the adjoining counties. There are seventeen well-produced plates and twenty-two maps and diagrams interspersed in the text.

As the title implies, this Handbook ranges over the whole of the Republic and does not concentrate on Dublin, the venue of the meeting, and its immediate surroundings. In this respect the book differs from its predecessors; but nevertheless the editors made a wise decision in this connexion. Some chapters, for example, physiography, geology and botany, range over the whole of Ireland (including Northern); others are confined to either the whole or just a part of the area south of the border.

Mr. J. P. Haughton has written a valuable survey of the physiography and climate of the entire island. Geology is treated by three authorities: Prof. J. C. Brindley on basement rocks; Prof. W. D. Gill on the Upper Palæozoic Systems; and Mr. G. F. Mitchell on the Pleistocene Epoch. Prof. D. A. Webb deals with the terrestrial flora, and Dr. M. de Valera and Miss H. M. Parkes describe the rich algal flora of the east and west coasts. The zoology of Ireland is so vast that in tackling this section Prof. C. F. Humphries and the Very Rev. P. G. Kennedy have wisely confined themselves mainly to the south-east. Inland fisheries loom large in the economy and sport of Ireland, so a separate chapter, by Dr. A. E. J. Went, deals with these. Thirteen families of fish are to be found in the fresh waters, the most important from the economic point of view being salmon, sea-trout and eels.

Prof. G. O'Brien writes on the economic structure of the Republic.

Agriculture, Ireland's main industry, is dealt with by three authors: Dr. J. J. Byrne, who presents a general survey; Dr. R. O'Connor, who writes about the small farms which abound there; and Dr. D. Twomey, who describes the important livestock industry. Peat is an important fuel in Ireland, so it is fitting that a chapter should be devoted to it in such a book as this. It was compiled for the Irish Peat Board by Mr. H. M. S. Miller, and is of special interest in dealing with peat winning, preparation and artificial dehydration.

The archæology of the Republic covers a wide field. Prof. S. P. Ó. Ríordáin deals with the prehistoric period, and Dr. F. Henry the early Christian period. Local traditions in Ireland are exceptionally fascinating, and still offer wide fields for research. Prof. J. H. Delargy describes the folk-lore in general; place-names are considered by Dr. M. A. O'Brien; and Mr. A. T. Lucas discusses folk-life. Prof. M. Dillon's excellent chapter on the Irish language as one of the Celtic group seems somewhat out of place in such a Handbook as this because most of the Association's visitors will have little time for studying it even cursorily, whereas any serious student would certainly wish for more.

The City of Dublin is covered in the last chapter by Dr. R. B. McDowell, who describes its growth; Mr. J. Meenan, who considers its role in the Irish economy; and finally by the two editors of the Handbook, Mr. J. Meenan and Prof. D. A. Webb, who present a useful, but all-too-short, account of the principal scientific institutions in Dublin, including the universities and colleges, learned societies, museums and botanic garden, etc.

Each chapter of the Handbook is followed by a very useful bibliography. It is a pity that there is no account of the development and present position of education in Ireland. But the most serious omission is that of an index. A Handbook of this sort, though handsome in appearance and making good arm-chair reading, is essentially a work of reference; and such a work must have an index if it is to satisfy its readers.

Taunton College School was still called the Free Grammar School.

In 1864, Queen Victoria appointed Lord Taunton as chairman of a Public Schools Inquiry Commission. At this time Lord Taunton was also president of the Board of Governors of King's. He called Tuckwell to give evidence before the Commission concerning the teaching of physical science at his school. In giving evidence, Tuckwell satisfied the Commissioners that a scientific education gave his pupils inestimable advantages in later life.

Tuckwell met with much adverse comment, and although he may not have realized it, his chief obstacle to teaching science in his school was that, in order to move the school to its present premises, a joint-stock company with a governing body had been formed. No longer was Tuckwell free, as he had been under the former constitution of the governing body. Under the old system, the headmaster had received an endowment, which was not accompanied by any sort of restrictions or obligations as regards his teaching or conduct. The duties of the trustees had been to appoint a headmaster, not to maintain the school. His governors grew to dislike this arrangement, with the College School "with a classical side trying to lead in the new science teaching". They disliked as headmaster "a pioneer in the teaching of science and a brilliant exponent of it against the old specialisation in classics". In the face of this, Tuckwell resigned at the end of 1877.

In 1880 the school was acquired by the Woodard Corporation and from that date until recently no startling advance was made; science teaching was continued, but no new facilities were introduced to keep pace with the rapidly expanding school.

However, in the late 1930's it was decided to build a new science block; plans were drawn up; materials ordered and work was due to start in October 1939; but the project had to be temporarily postponed. It was, however, necessary to have additional laboratory space of some description, and so a temporary wooden laboratory was erected, Tuckwell's old laboratory then being given over to the teaching of biology. This new laboratory served its purpose admirably, and in 1943 another of these laboratories was acquired, this being used for the teaching of physics.

After the War, a memorial fund was opened, and in 1947 it was decided that the war memorial and science block should be incorporated in the one building. In 1955, Tuckwell's old laboratory was pulled down to make way for the erection of the new block. When the building was started, £8,000 had been given to the fund, and £20,000 had been lent, by relatives of the bereaved and by friends of the school.

When first designed, the block was intended to consist of two chemistry and two physics laboratories only. However, in 1956 the Industrial Fund for the Advancement of Scientific Education in Schools gave the school a grant of £10,000, and so made it possible to extend the block to include two preparation rooms and a science library, and to fit the laboratories with modern equipment and apparatus. It is interesting to notice the difference in the floor space of laboratories; the new block has a total floor space of 6,000 sq. ft. as compared with the 300 sq. ft. of Tuckwell's old laboratory. The only reminder of the great pioneer who did so much for King's is a plaque set in the wall of the new block, approximately over the site of Tuckwell's laboratory.

GENETICAL HAZARDS OF RADIATIONS*

A YEAR ago I reviewed in *Nature* a report on the biological dangers of nuclear and applied radiations which had been prepared by the Medical Research Council and published by the Government. I concluded with an urgent appeal for an easily readable digest of this important document. However, no such help has been given to the public, which is getting more and more anxious to understand the position. Instead of this, there has been a plethora of statements by scientists which, unfortunately, has probably contributed more to the confusion than to the enlightenment of the public. For the technically trained reader it is easy to see that all these statements agree on certain fundamental facts and conclusions, but the emphasis is placed in such different ways that the general reader may well feel it is more or less a matter of choice or philosophy whether ionizing radiations are considered dangerous or not. Much of this confusion could be dispelled if a recent popular lecture by Dr. Warren Weaver, of the Rockefeller Institute, could be made available to the broadest possible public at the lowest possible costs.

In ten lucidly written pages, Dr. Weaver makes the reader acquainted with the indispensable scientific background to the problem of radiation hazards. He limits himself almost entirely to genetical hazards; the dangers to the immediately exposed persons are scarcely considered. It is true that this leaves out of consideration just those effects—like bone cancer caused by strontium-90 or leukæmia caused by diagnostic X-rays—which at the moment cause most concern. But these are also the dangers which can be most easily understood by the lay person, whereas the much more subtle and yet in no way less real genetical dangers are not easily appreciated. It is the great virtue of Dr. Weaver's lecture that it states quite clearly and unequivocally those basic facts of radiation-induced mutation about which there is general agreement. He summarizes them in a paragraph which seems so important to me that I should like to quote it in full: "First of all, the change produced by mutation is practically always a change for the worse. Second, the amount of mutation varies directly with the amount of radiation. Third, there is no minimum amount of radiation which is genetically safe—all radiation is genetically bad. A little radiation is a little bad, and a lot is a lot bad. Fourth, once exposed to some radiation, this never 'wears off'; this is to say, the genetically important number of mutations depends on the total dose that one accumulates from his own conception up to the time of conception of his last child. Fifth, the radiation that is important genetically is only that which reaches the gonads—that is to say, the male testicles and the female ovaries. Sixth, what counts from the point of view of society as a whole is the total number of mutated genes. Thus a small radiation dose to a large number of persons is, socio-genetically speaking, equivalent to a large dose to a few".

Finally, there is an excellent brief discussion of the reason why, in the face of this generally accepted situation, scientists yet differ among themselves in their assessment of radiation hazards.[1] This is only in part due to our lack of knowledge concerning the number of mutations which a given dose of radiation produces in man; in fact, the estimates of this quantity vary surprisingly little between scientists in Britain and in the United States. The main causes of divergent opinions are the personal attitudes to two problems: one temporal and the other numerical. The temporal: how large is our responsibility towards future, still unborn, generations of mankind? The numerical: granted that a certain dose of radiation is sure to cause the death of a few thousand babies in the next generation, do we need to worry about this when these deaths, for which we carry the responsibility, form only a very small proportion of 'natural' deaths? The answers to these questions cannot be dictated by the scientist; they have to be given by everyone according to his reason and moral standards. All the scientist can do is to put the facts before the public, and this has been done most ably in Dr. Weaver's lecture.

INSTITUTE OF PHYSICS

REPORT FOR 1956

THE thirty-seventh annual report of the Board of the Institute of Physics covering the work of the Institute during 1956 was presented to the annual general meeting of the Institute, which was held on July 12 at Oxford during the Institute's third convention. During the year under review the Board met six times and its various standing committees ten times. The membership and examinations committee dealt with 752 applications for election or transfer to the various grades of membership, and the interviews panel met three times and interviewed eleven candidates. Representatives of the committee visited four technical colleges which had applied for recognition by the Institute. The committee is now also responsible for giving advice on educational matters, and two panels have been set up—one to consider the revision of the lists of recognized qualifications for membership, and the other to submit a report to the Board on suggested means of stimulating entry to the profession of physics.

The total membership of the Institute rose during 1956 by 385 to 5,531, with the greatest increase in the associateship (203) and the graduateship (104) grades of membership. The graduateship examination was held during June 11–15, and written papers were taken both at the Institute's rooms in London and at three provincial centres. Seven of the forty-five candidates who presented themselves for examination satisfied the examiners. For the final examinations for National Certificates in Applied Physics the numbers of candidates were 424 for the ordinary level and 152 for the higher certificate, compared with 309 and 82, respectively, in 1955. The Board agreed to accept the diploma in physics of the Northern Polytechnic, London, as giving complete exemption from the Institute's academic requirements for graduateship membership. Five such diplomas had been accepted during 1955, three of which were to be awarded on satisfactory completion of sandwich courses. In co-operation with the London and Home Counties Regional Advisory Council for Higher Technological Education a conference on "Degree and Diploma Courses in Applied Physics" was arranged and held at the Institution of Electrical Engineers, London, during November 15–16. More than half the 160 who attended were senior representatives of industry or government service. The proceedings of the conference, including the discussion, have since been published, both in the Institute's *Bulletin* (8, 47, 86, 119, 166; 1957), and separately in booklet form. ("The Education of Physicists in Universities and Colleges of Technology": Institute of Physics, London. 1957. 6*s*.)

The increase in circulation of the Institute's two journals, *The Journal of Scientific Instruments* and *The British Journal of Applied Physics*, to libraries and non-members was about double that of the past few years, and the effect on the circulation of the new requirement that members pay for their own copies was less than anticipated. The revenue from advertisements showed a satisfactory increase. Details of the numbers of contributions submitted and published, together with the extents of the journals, are given in the annual report. The average delay between the first receipt and publication of a manuscript remained about six months. Supplement No. 5 of *The British Journal of Applied Physics*, containing the proceedings of the conference on "The Physics of Nuclear Reactors", held in London during July 3–6, was published in November.

The *Bulletin*, which has been expanded and presented in an entirely new and improved format during 1956, is now the only periodical of the Institute to which all members are entitled without extra payment, and its development is considered by the Board as an important part of the publication policy of the Institute. The twelve monthly issues comprised 344 pages containing twenty-three articles; news of the activities of the Institute's branches and groups; thirty-six book reviews; and the titles and abstracts of the principal contents of the Institute's two journals.

The Institute continues to be represented on many joint bodies and committees, including the Parliamentary and Scientific Committee, committees of the Royal Society and the British Standards Institution, and several national, regional and other scientific and technological advisory councils. Extracts from the reports of the Institute's representatives are given in the annual report. The number and nature of the inquiries addressed to the Institute concerning professional matters were much the same as in previous years. A fourth in the annual series of surveys of salaries and emoluments of members of the Institute was made in October and a report on the survey was published in the January issue of the *Bulletin* (8, 19; 1957). The annual inquiry concerning the type of posts taken up by new graduates in physics was extended in the case of 1955 graduates to include those with M.Sc. and Ph.D. degrees. A similar inquiry is being made in respect of 1956 and 1957 graduates, and it is hoped to publish a report, with comments, which will cover the results of these inquiries.

Details of the activities of the specialist groups and of the branches of the Institute, both home and overseas, are listed in the report. The Australian branch consists of 419 members and separate divisions in the various states of the Commonwealth. Under the auspices of the New South Wales division a conference on contemporary optics was held in Sydney during September 19–21 (*J. Sci. Instr.*, 34, 129; 1957). The inaugural meeting of the Malayan branch was held in Singapore on May 9 when Mr. C. G. Webb was elected chairman and Dr. Thong Saw Pak honorary secretary. The Liverpool and North Wales branch held a two-day symposium in Bangor during September 26–27 on the subject of nuclear magnetic resonance, at which it was decided to form a Radiofrequency Spectroscopy Group of the Institute to cover all branches of spectroscopy up to about 10^{11} c./s. The programme of the London and Home Counties branch included a joint symposium with the Royal Institute of Chemistry and the Institute of Biology on the presentation of science to the public, and visits to the National Institute for Medical Research, the Research Laboratory of Associated Electrical Industries, Ltd., at Aldermaston, and the Royal Naval College and the National Maritime Museum at Greenwich. A one-day conference on physics in industry was held in Cardiff by the South Wales branch at which Sir John Cockcroft gave a public address on "The Future of Science and Technology in Industry" (*Bulletin*, 7, 147; 1956). Joint meetings were held between the Education Group and the Manchester and District branch, and between the X-ray Analysis Group and the Low Temperature Group of the Physical Society; a symposium on thin films was held by the Electronics Group in Reading; and the summer meeting of the Non-Destructive Testing Group took the form of a symposium in Bristol on the physics of some new aspects of non-destructive testing, the contributions to which have since been published (*Brit. J. App. Phys.*, 8, Suppl. No. 6; 1957).

At the general meeting of the Institute, the following were elected to take office on October 1: *President*, Mr. O. W. Humphreys; *Vice-President*, Prof. E. C. Stoner; *Honorary Treasurer*, Dr. J. Taylor; *Honorary Secretary*, Prof. F. A. Vick.

WALL DEPOSITION IN *CHAETOMORPHA MELAGONIUM* (CLADOPHORALES)

By Dr. E. NICOLAI

Botany Department, University of Leeds

THE morphological complexity of the structure of the walls in several members of the Cladophorales attracted the attention of botanists as early as the middle of the past century, at a time when the light microscope was the only tool available. Since that time, the application of the more modern methods of X-ray diffraction analysis and electron microscopy has confirmed the older results and amplified them by adding structural details formerly beyond the limits of investigation. It is now known[1] that the walls of all the members of the Cladophorales —except the genera *Acrosiphonia* and *Spongomorpha* —are built up of many lamellæ each consisting of strictly parallel microfibrils imbedded in an amorphous matrix. The direction of these microfibrils changes from layer to layer through an angle of about 90°, so that by and large in every other layer the microfibrils are running in the same direction[2]. This structure, the 'cross-striation pattern', had been foreshadowed in the light-microscope observations of two sets of fine striations visible in surface view of the walls, reflecting exactly the directions of the two sets of underlying microfibrils[3]. Approximately the same structure occurs in the walls of *Valonia* where, however, a third direction of orientation is present, though the corresponding microfibrils are less abundant than are those in the two major directions[4]. In the filamentous Cladophoraceae, one of the sets of striations (and therefore one set of microfibrils) is approximately parallel and the other one perpendicular to the longitudinal axis of the cells.

X-ray analysis has shown that the microfibrils in the above-mentioned cases consist of highly crystalline cellulose I[2] and in *Valonia* this has been confirmed by electron diffraction analysis[5].

It is clear that any ideas on the genesis of this crossed fibrillar structure are best based on observations of walls recently formed at a previously naked cytoplasmic surface. The swarmers and the developing sporelings of members of the Cladophorales obviously offer suitable material on which critical observations might be made, and the present article concerns the data obtained about the first wall laid down and the stage of development at which the cross-striation pattern makes its appearance.

Two marine members of the Cladophorales were chosen because of the ease and reliability with which they form motile stages in quantity. One of them will be discussed here, *Chaetomorpha melagonium*. The unbranched filaments of this plant were collected on the Northumbrian coast, near the Dove Marine Laboratory in Cullercoats. The motile stages of reproduction can be either gametes, the fusion of which gives a zygote which in turn develops into a new plant, or zoospores which sprout without fusion. During the months of January and February, filaments brought from the coast, kept overnight in a refrigerator at about 2° C. and then returned to room temperature in the light, produced large numbers of motile cells. Many of the large cells of the filaments were emptied in the formation of about 8μ-long swarmers, each bearing two flagella. The presence of two flagella and the emptying of whole filaments both in the laboratory and on the shore suggests, on the basis of Hartmann's work[6], that these are gametes, though only very rarely could a beginning of fusion be observed. These swarmers, nevertheless, can be induced to settle and germinate. They keep moving for several hours and collect towards the light. Though they settle readily on solid substrates, it proved to be difficult to find a transparent medium on which they sprout and develop. The best results were reached with silica plates covered with sea water. On this substrate settling and sprouting of

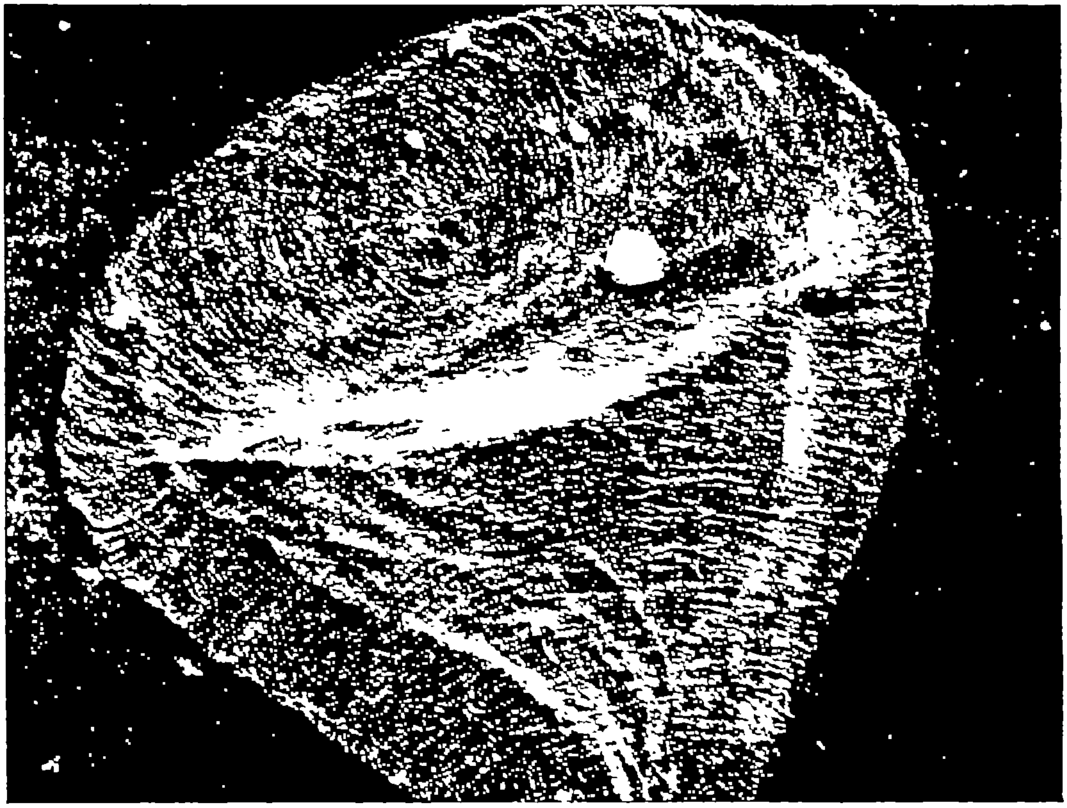

Fig. 1. Electron micrograph of the wall of a 24-hr. old sporeling of *Chaetomorpha melagonium*, after extraction of the contents. (× *c.* 11,800.) Shadowed with palladium-gold. The sprouting end is below the bottom of the photograph

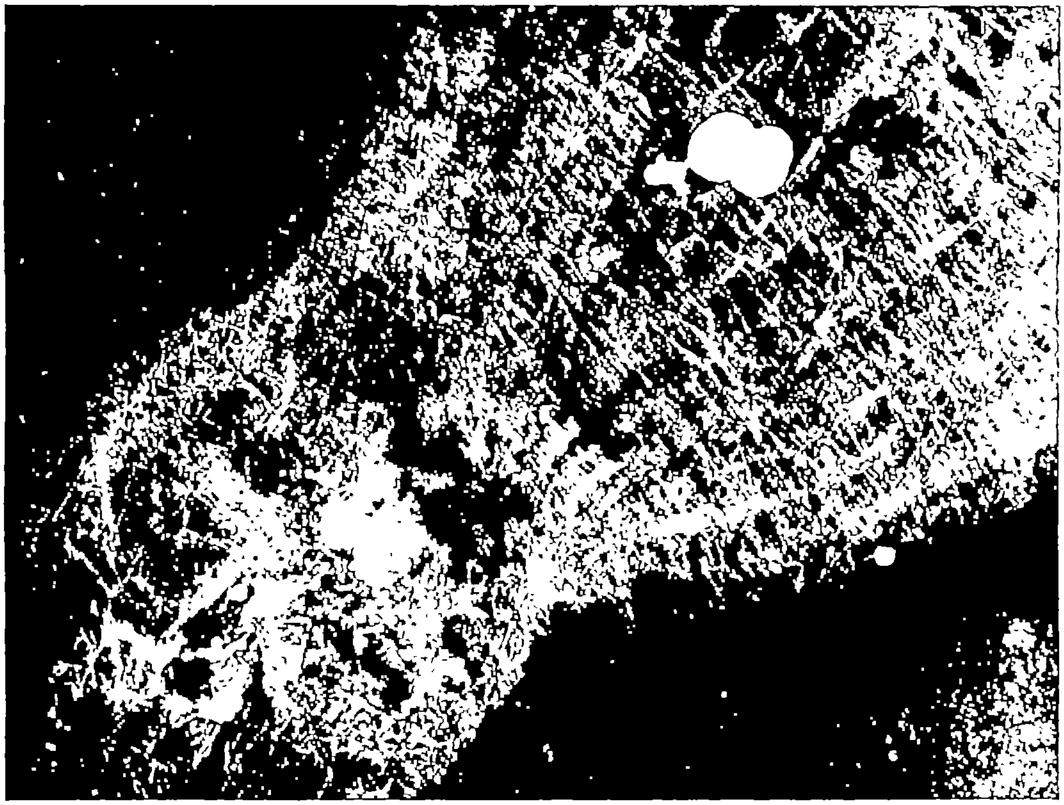

Fig. 2. Electron micrograph of the wall at the sprouting end of an 11-day-old sporeling of *Chaetomorpha melagonium*, after extraction of the contents. (× *c.* 17,500.) Shadowed with palladium-gold

the swarmers can be observed under the microscope, and the sporelings can be easily brushed off and collected at any stage required for investigation. The cultures were kept at a temperature of ± 5° C. in a special refrigerating unit provided with strip-lights and designed for the growing of algae.

Investigation of the structure of the different stages of development was carried out by means of X-ray diffraction analysis and by electron microscopy. For both methods large quantities of swarmers or sporelings had to be available.

X-ray diagrams were obtained by packing swarmers or sporelings into a hole about 1 mm. diameter in a 'Perspex' holder which was mounted over the slit of the X-ray spectrometer. Electron micrographs could be obtained only after pretreatment of the material, as the contents of the cells make them opaque to the electron beam. The extraction method used by Thimann and Bonner[7] in their investigation of coleoptiles proved to give good results in this case. The sporelings were washed in distilled water, boiled for about ½ hr. in water, kept for 24 hr. in a ½ per cent solution of ammonium oxalate at a temperature of 80° C. and then extracted successively in boiling 2 per cent sulphuric acid and in boiling 2 per cent sodium hydroxide. After thorough washing in distilled water, the material was caught on a specimen holder covered with 'Formvar' film and shadowed with palladium–gold. Electron micrographs of different stages of development of swarmers have been made.

(*a*) *Swarmers before settling*. Electron micrographs of swarmers caught on the 'Formvar' film while still swimming, dried and shadowed, present no features of importance since the contents are opaque to the electron beam. It is clear, however, that the cells have burst on drying, and that there is no trace of a wall or a boundary layer.

(*b*) *Swarmers after settling*. It can readily be observed in the light microscope that a wall is formed shortly after settling.

Electron micrographs of this material were taken within 24 hr. of settling. After extraction, the sporelings yielded clear pictures of an already well-developed wall (Fig. 1). The most striking observation at this stage is the presence of a well-defined pole opposite the region at which sprouting occurs, the beginning of which can also be observed already in this early stage. As the swarmers settle with their apical part (where the flagella were attached) to the substrate, and sprout, the pole must have developed at the posterior part of the original cell. Around the pole, coarse bands may be seen encircling the cell. On the outer side of these bands distinct and very thin microfibrils are present which are, however, isolated and infrequent. They tend to radiate from the pole and to converge towards the sprouting end, where after two days a random structure of well-defined fibrils is present. There is a suggestion of the presence of microfibrils in the coarse band structure below.

The next stage which proves to be of interest is that of the 11-day-old sporelings, which show after extraction a wall with a cross-striation pattern (Fig. 2). The more-or-less random microfibrils at the outside are still visible, and the original coarse bands around the cell now show microfibrillar structure, whereas towards the inside of the cell a second coarse pattern of broad, more or less opaque bands has developed, perpendicular to the first one. The fibrils in this pattern are still chiefly hidden in the opaque bands and are visible only occasionally. The sprouting part of the sporeling has increased in length and still has a random fibrillar orientation.

In comparing the X-ray diagrams of these stages of development note must be taken of the fact that only in the 11-day-old sporelings is a clear diagram of highly crystalline cellulose I obtained. In the younger stages vague rings are present corresponding to some of the spacings in cellulose I, notably the 3·9 A. and the 5·4 A. spacing. The ring corresponding to a spacing of 4·4 A. is by far the most prominent. Apart from these spacings, a few additional ones are present not belonging to cellulose I. Increase in age of the sporelings leads to a gradual decrease in the intensity of the ring corresponding to a 4·4 A. spacing, together with an increase in the intensity at 3·9 A. In the 11-day-old sporelings, the complete cellulose I diagram is present with all spacings in the correct relative intensity, whereas the additional spacings have disappeared. An electron diffraction pattern of a sporeling in this stage shows two crossed systems of orientated cellulose spacings.

One of the major points of interest in the development from motile stages to sporelings in *Chaetomorpha melagonium* is thus the presence of a pole in the very first stages of wall-deposition as the centre of a well-defined structure. In adult vesicles of *Valonia* the presence of a pole has been firmly established[4] only after many years of extensive research; in *Chaetomorpha* sporelings, however, electron micrographs show its presence without any shadow of a doubt. The structure of the encircling coarse and slightly opaque bands does not reveal the presence of well-defined microfibrils in the first instance.

After some time (in this case, 11 days), however, microfibrils are visible within these bands, though in several places they still seem to be cemented together by an opaque substance. The impression is gained that a crystallization of cellulose molecules to microfibrils with a cellulose I lattice takes place gradually within the bands. Whether some protoplasmic component is still, at first, intimately linked with the cellulose molecules and gives the above-mentioned X-ray diagram is a matter for speculation. It is certain that in the 11-day-old wall where the transverse bands show fibrils and where a second coarse and still partly opaque band structure has developed, perpendicular to the first one, a cellulose I X-ray diagram is recorded for the first time in the growing sporelings, whereas an electron diffraction pattern obtained from one cell shows the presence of two well-orientated systems perpendicular to each other.

During this development the outer part of the wall still shows the random fibrils which probably are not built of cellulose I, as the X-ray diagrams in the first stages did not show the cellulose I spacings.

I wish to acknowledge with gratitude the valuable contribution of Mr. G. W. Ripley, who took the electron micrographs, and my sincere thanks are due to Prof. R. D. Preston for his continued help and advice.

A Suggested Statistical Model of some Time Series which occur in Nature

The following is an amplification and extension of some work which was described in a general way at a symposium of the Research Section of the Royal Statistical Society on Storage Problems on March 6, 1957.

Annual values of some phenomena such as river discharges, rainfall, temperature, are approximately normally distributed if no account is taken of order of occurrence. Their principal characteristic, however, is the occurrence of periods when, on the whole, values tend to be high and others when they tend to be low, though low values may occur in a high period and vice versa. So far as is known, there is no regularity in the occurrence or the length of these periods, and usually there is no significant correlation over one of them between a year and its successor.

This phenomenon is important in problems of storage. In these a quantity R enters, which is obtained by taking departures of the annual values from their mean for a period of N years, and plotting the continued sums of these departures against the numbers 0 to N. The range of this curve is R and is easily seen to be, in the case of a river, the storage capacity which would have been necessary to enable the mean discharge to flow in every year of the period. In the case of natural phenomena, of which about a hundred have been examined[1], the following equation represents the mean result:

$$R/\sigma = (N/2)^K \qquad (1)$$

where σ is the standard deviation and K is a quantity which has a normal distribution and the mean of which is 0·73.

If, however, the quantities considered are entirely independent events, such, for example, as would arise from tossing a set of, say, twelve coins and recording the differences between the number of heads and number of tails at each throw, R is represented by the following equation:

$$R/\sigma = \sqrt{\tfrac{1}{2}N\pi} = 1{\cdot}25\sqrt{N} \qquad (2)$$

The values of R are the same from the two equations when $N = 22$; but for higher values of N the value of R from equation 1 steadily increases at a greater rate than does R from equation 2. For $N = 100$ the difference is about 25 per cent, and for $N = 1{,}000$, 100 per cent. There is therefore a definite difference between many natural time series and those where the terms are independent of each other.

An apparatus by which either type of series can be imitated is a pack of what I have called 'probability cards'. The first pack contained fifty-two cards numbered ± 1, ± 3, ± 5, ± 7, and the numbers of each kind of card were thirteen of the ones, eight of the threes, four of the fives, and one of the sevens. These numbers are proportional to the ordinates of the normal curve corresponding to departures of 1, 3, 5 and 7 from the mean 0. If cards are cut from this pack, shuffling after each cut, a series of random numbers will be produced which will conform to equation 2, and this has been found to be the case[1].

If, however, the following procedure is adopted, a different result will be obtained. The pack is shuffled and a card is cut, and after its number is noted it is replaced in the pack. Two hands are then dealt, and if, for example, the card cut was + 3, the highest three positive cards in one hand are transferred to the other, and the highest three negative cards are removed from it. This hand then has a definite positive bias. A joker is now placed in it and it is shuffled and a card cut from it. The number on this card is the first of the series. It is replaced and the hand then reshuffled and another card is cut and recorded. This cutting and shuffling goes on until the joker is out. Then the joker is removed and all the cards are put together and shuffled, after which the process is repeated. The amount of bias, the number of cuts for which the bias acts, and the actual cards which turn up all depend on random processes.

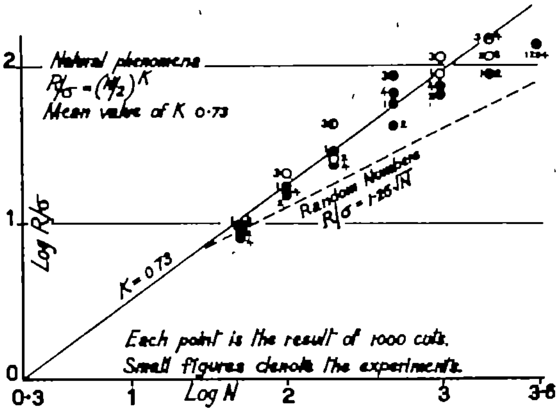

Fig. 1. Cutting probability cards. Pack of fifty-two. Biased hand of twenty-six cards + joker

Four different experiments of 1,000 cuts each were carried out. From each of these R was determined for twenty sections of fifty cuts, ten sections of a hundred, nine overlapping sections of two hundred, etc. The points up to $N = 1{,}000$ are the means of these sets. The four experiments were combined in order of occurrence so as to give values for 2,000 and 4,000 cuts. The results are shown in Fig. 1, where small figures alongside the observed points indicate to which experiment they belong. The mean value of K from all experiments is 0·71.

The card experiments have not been fully analysed as to variation of means and standard deviations, and further experiments are also being made. The result, however, indicates that the process described leads to time series very similar to those which occur in Nature.

Velocity of the Seismic Waves *Lg* and *Rg* across Australia

An examination has been made of *Lg* and *Rg* phases recorded over continental paths in Australia. The results which are here presented show some striking agreements with the earlier work of Ewing and Press[1] for North America and of Båth[2] for Eurasia.

The "International Seismological Summary" lists seven Australian earthquakes well recorded overseas, namely, the two Western Australian ones of August 16, 1929, and April 29, 1941, and the five Central Australian ones of December 20, 1937, April 17, 1938, March 26, 1939, May 4, 1941, and June 27, 1941. The epicentres and origin times of these earthquakes were revised using the method of Jeffreys and Bullen[3]; (the shock of March 26, 1939, has previously been discussed[4]).

The Riverview Observatory records of these seven earthquakes and of the Adelaide earthquake[5] of March 1, 1954, were those examined; the records were from Weichert instruments in the case of the first seven, and Galitzin instruments in the last case. The *Lg* phase was found to be recorded in the case of all earthquakes except that of August 16, 1929, a marginal earthquake off the north-west coast. The *Rg* phase was clear only for those of May 4, 1941, and March 1, 1954. (The *Lg* and *Rg* phases were identified in all instances without prior calculation of their expected arrival times.)

The mean *Lg* group velocity was 3·50 ± 0·08 km./sec. for seven observations from the vertical component instruments, and 3·50 ± 0·06 km./sec. for thirteen observations from the horizontal component instruments. In most cases the *Lg* phase was predominant on the records and its start had been given as an impetus onset in the *Riverview Seismological Bulletin*. Its initial period was 3–6 sec. The mean *Rg* group velocity was 3·03 ± 0·07 for three observations.

Press and Ewing, using about forty earthquakes, have given the mean group velocities of *Lg* and *Rg* over North American paths as 3·51 ± 0·07 and 3·05 ± 0·07 km./sec. respectively. For Eurasia, using about four hundred earthquakes, Båth has found at least two distinct *Lg* group velocities, namely, 3·54 ± 0·07 km./sec. and 3·37 ± 0·04 km./sec. Båth also found a mean *Rg* group velocity of 3·07 ± 0·10 km./sec.

The Australian data do not indicate strongly any separation of the *Lg* phase; only the earthquake of June 27, 1941, showed an *Lg* velocity, namely, 3·38 km./sec., which differed from the mean by more than the standard error. The combined mean Australian *Lg* velocity is 3·50 ± 0·07 km./sec., in striking agreement with the North American and Eurasian results. The importance of the present results is that they indicate that *Lg* and *Rg* velocities of order 3·50 and 3·05 km./sec. respectively are fairly world wide.

I am indebted to Fr. T. N. Burke-Gaffney, director of the Riverview Observatory, Sydney, for kindly making available the relevant records.

An Attempt to detect Linearly Polarized Radio Emmision from the Galaxy

Several authors[1,2] have suggested that synchrotron radiation by relativistic electrons in galactic magnetic fields may be responsible for part of the galactic background radiation at radio-frequencies. Radiation so produced is linearly polarized in a direction perpendicular to the magnetic field. The actual polarization observed from an extended region is likely to be reduced due to a number of mechanisms[3,4] which will be discussed elsewhere, but a small percentage might remain. Razin[5] has described an attempt to measure this polarization by a method based on the suggestion that the Faraday effect in interstellar space would make the angular position of the plane of polarization strongly dependent upon frequency. By switching between a wide and a narrow receiver band-width, a change of output was noted which was interpreted as implying the presence of up to 4 per cent of linear polarization in some directions. On present evidence, the magnitude of the galactic magnetic field and of the electron density in interstellar space[4] are thought insufficient for this dependence on frequency to lead to a reliable method of measurement, and a different procedure has been adopted. In the present method, a receiver band-width of 4 Mc./s. has been used, and although in certain circumstances the wider band-width might lead to a reduction of the polarization observed, the sensitivity is much improved, particularly when observing in directions away from the galactic plane.

A 7·5-m. paraboloidal reflector mounted as a transit instrument was used, at a frequency of 159·5 Mc./s.; at the focus, two dipole and reflector systems were mounted with their planes at right angles. This assembly was motor-driven about the axis of symmetry of the aerial system at a speed of one revolution in 27 min. The dipoles were connected to a phase-switching receiver[6] which gives an output proportional to the time average of the product of their voltages. For linearly polarized radiation incident along the axis of the system, correlated voltages appear in the dipoles and an output is produced; randomly polarized radiation along the axis produces uncorrelated voltages and gives no output. As the dipoles rotate, a sinusoidal record is produced, and from the amplitude and phase of this record the magnitude and position angle of any linearly polarized component may be determined. For this type of aerial system, intense randomly polarized radiation from directions off the axis of the aerial does, however, give a small response. Hence when the system is used to examine the galactic background radiation, a spurious apparent polarization may be produced. The magnitude of this effect has been estimated using the sun as source, and the observed effects agree with those estimated.

In order to overcome this difficulty, use has been made of the rotation of the plane of polarization by the Faraday effect in the terrestrial ionosphere, and the initial observations have been made at a declination of 22° N. where the line of sight is parallel to the geomagnetic field. Observations were made throughout the month of February 1957, and the progressive displacement of the solar time of observation of any particular point in the sky results in the observations being made through a progressively varying amount of ionization. This change of total ionization along

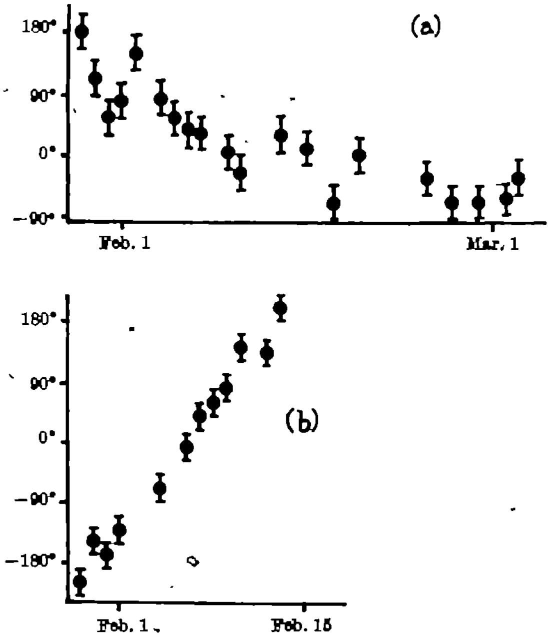

Fig. 1. Plots of the position angle against time of the planes of polarization for the areas centred on (*a*) R.A. 05h., declination [illegible]° N.; (*b*) R.A. 18h., declination [illegible]° N. The origin of the ordinate corresponds to polarization in the plane of the meridian

the line of sight causes a progressive rotation of the plane of polarization of any polarized component that may be present, while the spurious deflexion is unaffected. Diurnal curves of total electron content up to the maximum of electron density (Thomas, J. O., private communication) showed that during the month about one complete rotation of the plane of polarization would be expected, both in the evening when the electron content is declining, and in the early morning when it is increasing. Observations made during the former time should be more reliable, because the sun is then below the horizon; morning observations with the sun in the sky are complicated by a further spurious effect due to the direct reception of solar radiation by the primary dipoles. A vector construction was used for separating the rotating component due to actual polarization from the spurious effect.

The area in transit in the evening was from 04h. to 08h. R.A., a strip crossing the galactic plane approximately at the anticentre, where the brightness temperature is about 400 deg. K. An upper limit of 1 per cent can be put to the polarization throughout most of this region. It is believed, however, that linear polarization of the order of 1 per cent may have been detected at 05h., a region about 10° south of the galactic plane close to the anticentre. The area in transit in the morning was that around 17h.–18h., on the bright large-scale feature of the galactic emission described by Baldwin[7] and others, which rises from the galactic plane at about $l = 15°$. Here the brightness temperature is about 650 deg. K., and again it is believed that polarization of the order of 1 per cent has been detected. Fig. 1(*a*) and Fig. 1(*b*) show plots against time of the position angle of the plane of polarization for the regions near 05h. and 18h. respectively. The variation of the position angle in each case is in the direction to be expected from ionospheric data (Thomas, J. O., private communication), and is of the expected order of magnitude.

This work was carried out as part of a programme of radio astronomical research at the Cavendish Laboratory, supported by the Department of Scientific and Industrial Research, during the tenure of an Isaac Newton Studentship. I am indebted to Mr. M. Ryle and to Dr. F. Graham Smith for their help and advice at every stage of the work.

Arrays with Constant Beam-Width over a Wide Frequency-Range

In many sound-ranging and listening systems (principally used under water) it is necessary to receive signals over a wide range of frequency, the ratio of upper to lower frequency being of the order of ten or more. Transducers (or hydrophones) with a sufficiently wide frequency response are available, but usually have to be used as omni-directional receivers because otherwise their beam-width would be inversely proportional to frequency. Clearly, the use of directional receivers would be very advantageous in many applications, but an essential condition is that the beam-width must be constant over the appropriate range of frequencies. An approach

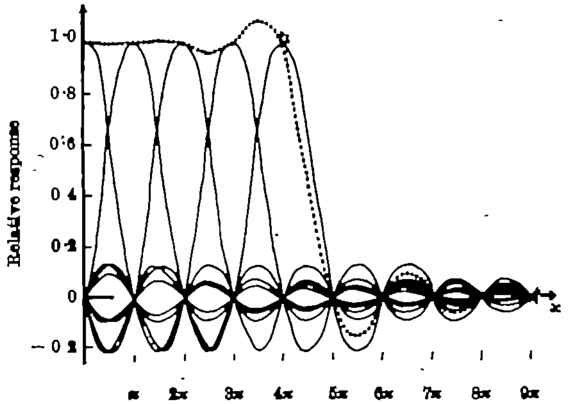

Fig. 2. Right-hand half of beam patterns at upper frequency limit for $r = 4$; $a_m = 1$ for all values of m. Component patterns, ———; resultant pattern, ... It is assumed that the number of sections in the array is large

to the solution of this problem is to connect the outermost units of the transducer to the receiving amplifiers through low-pass filters, so that the transducer is virtually made smaller at the higher frequencies. There are, however, many difficulties and complications in this process, which is, at best, rather crude.

A more elegant solution of the problem, and one in which the design problems are more straightforward, can be applied in the case of strip (or line) transducers, which are more suitably referred to as arrays of individual small transducers arranged in a straight line. Directionality is achieved in all planes containing the line of the array. The solution is based on the synthesis[1-3] of directional patterns from elementary $(\sin x)/x$ patterns using delay lines to produce these patterns at various angles of deflexion from the normal. The basic idea is that when the beam-width between half-power points is to be constant over a frequency range of ratio $2r + 1$, then $2r + 1$ patterns are superposed. One of these is the straight undeflected pattern of the array and the remainder is the set of patterns obtained from the $2r$ outputs of r delay lines. There must be a minimum of $2r + 1$ sections (or elements) in the array. The way in which these are connected is shown in Fig. 1 for $r = 4$ and for a 19-section array. Beam deflexion angles will be quoted in terms of x, where $x = \frac{l\pi}{\lambda} \sin \theta$, l being the length of the array, λ the wave-length, and θ the angle of any physical direction with respect to the normal to the line of the array. Each delay line has a phase-shift which varies linearly from zero at the lower frequency limit to a value at the higher frequency limit which causes a beam deflexion of π rad. on the first delay line, 2π rad. on the second, and so on until the final delay line, where it is $r\pi$ rad. It is shown in ref. 1 that to give a deflexion on the x-scale of π rad., the total phase-shift in the delay line has to be 2π rad., assuming the number of transducer sections in the array is large.

The patterns need not all have the same amplitude, although symmetry should be preserved. If the outputs of the mth delay line have a relative amplitude a_m, then it is clear that at the lowest frequency, where the phase-shifts are zero, the overall pattern is merely

$$\left[\sum_{m=-r}^{m=+r} a_m\right] \cdot \frac{\sin x}{x}$$

As the frequency increases, so the patterns derived from the delay lines are spread out from the axis of the beam, thus widening the beam on the x-scale at the same rate at which the x-scale itself increases relative to the physical angles (θ) due to the decreasing wave-length (λ). A constant beam-width thus tends to be maintained. (An increase of frequency beyond the design maximum will separate the patterns so that dips occur in between them.) If we take the minimum frequency to have unity angular velocity, so that the highest frequency has the angular velocity of $2r + 1$, then at any frequency the directional pattern is

$$D(x) = \sum_{m=-r}^{m=+r} a_m \cdot \frac{\sin [x - m(\omega - 1)\pi/2r]}{[x - m(\omega - 1)\pi/2r]}$$

If $a_m = 1$ for all values of m, then a very flat-topped beam is obtained at the upper frequency, as illustrated in Fig. 2; and an almost exactly constant beam-width (measured between the half-power points) and a fairly constant directivity index are maintained. To maintain a reasonably constant shape of beam—as well as a fairly constant width—over the frequency range, a_m should diminish as m increases; but if the shape is to be maintained outside the half-power beam-width, then additional delay lines will be needed to give additional component patterns of greater angular deflexion.

The method may well also have applications in radio aerials.

Adiabatic Piezo-Optic Coefficient of Heavy Water

AMONG the physical properties of heavy water, its refractive index, which has been studied widely, has been utilized quite often for the estimation of heavy water content, although other methods, such as infrared absorption, are also used. But the change of refractive index of heavy water with pressure was studied recently by us, and in view of its significance for the formulation of any theory for the optical properties of liquids we present here a brief account of the constants for ordinary water and heavy water.

The adiabatic piezo-optic coefficient was determined by an interferometric technique[1] employing a Rayleigh–Zeiss refractometer, and adequate precautions were taken to eliminate errors due to expansion of the cell, etc. The measured value of the adiabatic piezo-optic coefficient for sodium D line (5893 A.) was $10 \cdot 51 \times 10^{-6}$ per atmosphere for heavy water (purity 99·8 per cent) as compared to $14 \cdot 66 \times 10^{-6}$ for ordinary water[1]. Since the expansion coefficient for this concentration of heavy water was not available in the literature, a dilatometric measurement of the same was also made. These values along with other relevant constants are

Table 1

* Luten.

shown in Table 1 along with the corresponding values for ordinary water. The temperature variation of the refractive index of heavy water was measured by the usual method with the aid of a Pulfrich refractometer.

As has been pointed out earlier, the Lorenz–Lorentz refraction formula presupposes the refractive index to be a function of the density alone, and accordingly

$$-1/\alpha\left(\frac{\partial n}{\partial t}\right)_p = \frac{1}{\beta_\varphi}\left(\frac{\partial n}{\partial p}\right)_\varphi = \frac{1}{\beta_t}\left(\frac{\partial n}{\partial p}\right)_t = \frac{(n^2-1)(n^2+2)}{6n}$$

That the experimental facts are not in accordance with this has been shown by the measurements of Raman and Venkataraman[1] and the more recent investigations in this laboratory[2]. For water the difference between $\frac{1}{\beta_\varphi}\left(\frac{\partial n}{\partial p}\right)_\varphi$ and that predicted by the Lorenz–Lorentz relation is 0·0449, this difference for heavy water is nearly three times as much, namely, 0·1374. Further, detailed analysis shows that none of the other common refraction formulæ such as Newton–Drude, Gladstone–Dale and Eykman satisfactorily account for the observed piezo-optic behaviour of all the liquids. This has been attributed to the neglect of a pure temperature effect on the refractive index at constant density, as can be seen from the fact that the usual refraction formulæ do not account for the measured value of $-\frac{1}{\alpha}\left(\frac{\partial n}{\partial t}\right)_p$. The pure temperature effect for heavy water $(\partial n/\partial t)_\varphi$ as calculated from the experimental value of the adiabatic piezo-optic coefficient turns out to be $-2\cdot8 \times 10^{-6}$, that is, 35 per cent of the value of $(\partial n/\partial t)_p$, while for ordinary water it is only about 20 per cent. Also, unlike in the case of water, for heavy water the value of $-\frac{1}{\alpha}\left(\frac{\partial n}{\partial t}\right)_p$ is less than that predicted by the Lorenz–Lorentz formula. From their measurements of the piezo-optic coefficients of liquids and the deviation from the Lorenz-Lorentz formula, Raman and Venkataraman pointed out the influence of association, polarity of the molecules and the anisotropy of the polarization field, and have emphasized the fact that the maximum deviation occurred in the case of carbon disulphide, a highly polar liquid. However, it is sufficient to mention that though the dielectric constants of ordinary water and heavy water are nearly the same, the deviations from the theory of refraction are far greater in heavy water. It leads us to conclude that while association may influence considerably the piezo-optic behaviour of liquids, it is the local anisotropy of the field around any molecule and the consequent changes in the polarizability of the molecules that should be taken into consideration in any theory for the optical properties of liquids[3].

A detailed paper on this subject describing the results obtained with other liquids also will be published in due course in the *Journal of the Indian Institute of Science*.

Our thanks are due to Dr. H. J. Bhabha, head of the Atomic Energy Establishment, India, for placing at our disposal the requisite quantity of heavy water.

Study of Strain Distribution in Metals by the Determination of Local Electrode Potentials

When a piece of metal has been subjected to local plastic deformation, as, for example, by indentation, it is important in research work to be able to determine the distribution of strain and the elastic–plastic boundary. At least five methods are available for these determinations, and Williams and O'Neill[1] recently published results using explorations by low-load hardness tests. Samuels and Mulhearn[2] have pointed out the defects of some of the existing methods.

It occurred to one of us that determinations of local electrode potential of the deformed metal as used by Spring in 1903 might provide a further method of studying strain distribution. The method is known to have certain difficulties, but a prelim-

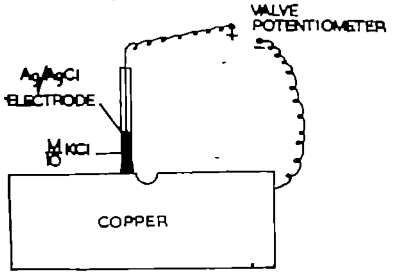

Fig. 1. Arrangement of electrode

inary test was made along the flat surface of a cylinder of annealed electrolytic copper which some years previously had been indented at its centre with a 10-mm. steel ball. The surface was cleaned with cotton wool and acetone, and the potential measurements were made with reference to a silver/silver chloride electrode as shown in Fig. 1.

The 'Pyrex' tube (internal diameter, 2 mm.) containing the electrode was immersed in $M/10$ potassium chloride and on withdrawing the electrolyte remained in it to a depth of 2 cm. The tube was then made to touch the copper surface momentarily, and on lifting it about 1 mm. from the surface, a liquid junction formed enabling potential measurements to be made. The potential of the specimen against that of the reference electrode rose with time but reached a reproducible steady value in ten minutes. This steady potential was found for various positions of the electrode on the copper surface. The potential in the impression itself and up to a distance of about 2½ cm. around it was anodic to the outside of the specimen, the difference between them being 10–12 mV. The values obtained for one filling of the tube in the sequence in which they were determined are given in Table 1.

Table 1

Distance from edge of impression in mm.	Potential versus Ag/AgCl in mV.
3	−190
7	−187
14	−187
Elastic/plastic boundary	
25	−180
37	−179
Inside impression	−190

Although the effect is small, it is reproducible, and should provide a method of exploring strain distribution. The test confirms the general results of Goerens[3] and of Simnad and Evans[4] for steel. Work is continuing on heterogeneous alloys.

Relativity and Space Travel

MAY I suggest an alternative approach to this problem making use of the Fitzgerald–Lorentz contraction? Consider as before a pair of twins, one of whom (Traveller) makes the pilgrimage to Alpha Centauri, four light years away, and the other (Stayathome) does not. Before starting they set up identical crystal-controlled short-wave transmitters by means of which they can follow each other's progress and, with suitable frequency-dividers, operate their clocks.

Traveller now accelerates very quickly to, say, 99 per cent of the speed of light. Both twins will agree that their transmitters make only a small number of oscillations during the acceleration. (To decide whether their transmitters make the *same* small number of oscillations would involve the introduction of general relativity, which I do not propose. Whatever difference of clock-*times* this produces, can be swamped by differences due to change of clock *rates* if Traveller's journey is long enough.)

After the accelerations, each observes that the other's inertial frame is much contracted along the line of travel. For Stayathome this only means that his brother's spaceship looks some seven times shorter than it did. To Traveller it is now clear that the distance between Earth and Alpha Centauri is just under seven light-months—although the fact that Alpha Centauri's radiation is now mostly in the far ultra-violet makes recognition difficult. He sees, as expected, however, that Alpha Centauri is approaching him, and Earth leaving him, at 99 per cent of the speed of light. Consequently, the goal arrives and Traveller has to decelerate after seven months of Traveller's time, during which his transmitter has emitted seven-months-worth of oscillations. Having arrived at Alpha Centauri, therefore, Traveller is quite clear that he is only seven months older than when he started. He now re-accelerates to 0·99 c towards Earth. Again, the Fitzgerald–Lorentz contraction of the rest of the universe leads him to see Earth advancing towards him from a distance of only seven light-months; again his transmitter emits only seven months-worth of oscillations before Earth reaches him, and he decelerates to arrive just fourteen months older than when he started. Depending upon his degree of relativistic orthodoxy, he may or may not be disturbed to find Stayathome nearly seven years older than himself.

Whether or not they are disturbed, the brothers will not be surprised if they have been observing each other's signals regularly. During the outward journey the signals received by each brother from the other's transmitter have, of course, moved into the (same) long-wave region, at about 14 times lower frequency than the original.

While the frequencies observed are symmetrical, the times for which they are observed will differ. Stayathome observes his brother's ship travelling away from the Earth until he sees its arrival at Alpha Centauri. This arrival, in Stayathome's time, is a little more than four years from the start, but he does not observe it until the light has had time to return to Earth, that is, more than *eight* years from the start.

Traveller on the other hand, receives these long waves for seven months only of *his* time. As soon as he has started on the return journey, he notices a huge rise in the frequency of Stayathome's signals, to about 14 times its normal value. Traveller continues to observe these very-high-frequency signals for the whole seven months of Earth's return journey, as during this return he meets all of the waves which Stayathome has sent out in more than eight years. (Only the waves emitted by Stayathome during the first 0·04 year managed to catch up Traveller before he reached his goal.)

Stayathome, however, sees this same high frequency for a far shorter time. The turn-around signal from Alpha Centauri takes four years to arrive, and the ship itself takes only 0·04 year more. Consequently, he observes the high frequency for 0·04 year or 0·48 month only, against Traveller's whole seven months.

Thus, when they compare notes, Traveller has picked up a full 8·08 years worth of oscillations, while Stayathome has picked up only $(8{\cdot}04 \times 1/14) + (0{\cdot}04 \times 14)$ years—or nearly fourteen months-worth.

It only remains to mention a possible reason for the long continuance of the misunderstanding. Attention to the asymmetry of comfort due to the extremely 'high-*g*' take-off of Traveller, which all parties agree takes a negligible period in either time, has diverted attention from a more important asymmetry. This is that both goal and origin are in Stayathome's inertial frame, and we can record events at either of them in Stayathome's time without ambiguity. To give complete symmetry, we need to suppose a second space ship, presumably a Flying Saucer, coming from the side away from Alpha Centauri. It must be moving at the same velocity as Traveller and at such a distance that Traveller sees it to be four light-years behind him. Then to Stayathome, for whom the Traveller–Saucer frame has suffered a Fitzgerald–Lorentz contraction, Traveller and Saucer appear to be just under seven light-months apart. Accordingly, Stayathome observes Saucer's invasion of Earth seven months after Traveller's departure, when Traveller is only one-seventh of his way to Alpha Centauri. Traveller, however, considers that the Flying Saucer invasion occurs after four years of his (and Saucer's) time (by which time, having changed his mind about return, he has left Alpha Centauri far behind).

Thus we see that the conceptual problem underlying the controversy is the same as that involved in any of the standard paradoxes concerning the apparent simultaneity of separated events in different inertial frames.

J. H. FREMLIN

Physics Department,
University of Birmingham.

I HAVE received several calculations similar to Dr. J. H. Fremlin's. To follow them through in detail is subtle and tedious, but it is unnecessary because it is at once obvious that since all the effects concerned are effects only of the relative motion of Stayathome and Traveller, and the motion of one is the mirror image of that of the other (for every stage of Traveller's motion, whether uniform or accelerated, there is an exactly corresponding stage of Stayathome's motion), there cannot possibly be any difference in the numbers of oscillations received.

Dr. Fremlin is right in ascribing many of the false conclusions which have been reached in this matter to the unconscious introduction of an asymmetry into what is essentially a symmetrical situation, but I do not think he has correctly identified that asymmetry. In saying that "both goal and origin are in Stayathome's inertial frame", he shows that he shares a common misunderstanding of the essential principle of relativity theory. Phenomena are not in any frame: we can place them in whatever frame we find convenient. What he means is that goal and origin (presumably goal means Alpha Centauri and origin the Earth) are relatively at rest: that is a fact which is quite independent of frames of reference.

Nevertheless, he comes near the essence of the asymmetry, which is that the halfway stage of the journey is, in the ordinary presentation of the problem, marked by an event (Traveller's arrival at Alpha Centauri) at which Traveller is present, and can, therefore, *observe* the time in his rest-system, while Stayathome is absent, and can only *calculate*, by the conventional definition, the time in his rest-system. Dr. Fremlin has himself shown how this artificial asymmetry can be reversed by marking the half-way stage by the arrival of the Earth at a Flying Saucer instead of the arrival of Traveller at Alpha Centauri. He spoils it, however, by saying that "Traveller . . . considers that the Flying Saucer invasion . . . (by which time, having changed his mind . . .)". Traveller considers the invasion to be an Earth invasion of Flying Saucer, and he does not change his mind at all: he sees the Earth immediately leave Flying Saucer and return to him. All Dr. Fremlin's previous reasoning then requires that the returning Stayathome will have aged seven months, and Traveller four years. I have shown this in a paper which will appear in the *Australian Journal of Physics* of September. To give the problem greater verisimilitude, instead of the Earth and stars I have considered an engine, *M*, travelling between two stations, *A* and *B*. The engine has a train attached, of rest-length equal to *AB*. When the turning-point is marked by *M*'s arrival at *B*, *M*'s clock is behind the time calculated according to the clock in *A*. When, however, it is marked by the arrival of the last truck, *G*, at *A*, the clock in *A* is behind the time calculated according to the clock in *M*.

If Dr. Fremlin will reconsider his statement that "both goal and origin are in Stayathome's inertial frame, and we can record events at either of them in Stayathome's time without ambiguity", I think he will see that he is unconsciously supposing that Stayathome's time is somehow superior to Traveller's. You can record events in *any* given time system without ambiguity. Ambiguity comes in when you have to choose between different systems, and you cannot resolve it by arbitrarily deciding for one of them.

Purley, Surrey.

Rocket Observation of X-Ray Emission in a Solar Flare

THE report[1] of normal Lyman alpha- and enhanced X-ray emissions from the Sun during a solar flare on July 20, 1956, presents several problems in connexion with observations of ionospheric absorption as well as the physics of the solar corona.

As is well known, during many flares the cosmic noise received on 18-Mc./s. drops sharply in intensity. The magnitude of the decrease can be used to derive information on the corresponding fractional increase in electron density through the absorbing layers of the ionosphere. On July 20, 1956, at 1905 U.T., our cosmic noise records showed a slight decrease in flux level, which fell at 1912 U.T. to its lowest value, about 93 per cent of the average over the preceding and following hours. The normal flux level was re-established by 1920 U.T. If we assume that the fractional increase in electron density was constant through the *D*-region, the maximum increase therefore amounted to about 7 per cent. On the other hand, the maximum increase during a typical cosmic noise absorption can be several hundred per cent. Chubb *et al.* state that the observed X-ray increase should have doubled the electron density between heights of 75 and 95 km. Such an increase is far greater than the increase consistent with our records. If we allow the possibility that the fractional change in electron density varies with height, the function must increase sharply above the 75–80 km. level where the principal contribution to the absorption usually occurs. In this way it would be possible to have a large increase in electron density without corresponding increase in absorption. But if this were so, then the X-ray effects of the flare would modify the height distribution of electrons at the wrong heights for an explanation of the lowering of the *D*-region as determined by the method of phase anomalies.

On a purely Lyman alpha theory of the origin of the cosmic noise absorption, we would conclude that the total solar output was $(1 \cdot 07)^2$ times normal, a virtually undetectable (personal letter from H. Friedman) increase of only 14 per cent, even if the rocket had flown during the maximum phase of the cosmic noise absorption.

We now consider the relative merits of the Lyman alpha- and X-ray mechanisms for sudden ionospheric disturbance (S.I.D.) effects. Chubb *et al.* point out that some large flares do not show S.I.D. effects, and that this fact argues against the Lyman alpha mechanism for the production of the S.I.D. However, C. S. Warwick[2] has shown that the chromospheric opacity, combined with the varying heights of solar flares, provides a natural explanation for this phenomenon. This explanation cannot be used for X-ray effects, since the chromosphere is relatively transparent to X-radiation.

In order to explain the ionospheric effects, the Lyman alpha flux during a flare must increase by several orders of magnitude, corresponding to a flare excitation temperature between 2×10^4 and 3×10^4 deg. K. Observations[3] of flare kinetic temperatures yield values in excess of 3×10^4 deg. K. On the Lyman alpha hypothesis, during the largest flares, the total flare output is about 10^{28} ergs/sec., which is 10^{-5} solar constant. Although this may seem large, the cosmic-ray energy alone of the outstanding flare event of February 23, 1956, amounted[4] to some 10^{27} ergs/sec. In Lyman alpha we deal with the resonance line of the most abundant atom in Nature and therefore expect a much greater energy. Furthermore, flux of this order of magnitude explains[5] simply and directly the rectilinear motions and support of the outstanding prominences associated with flares.

There appear to be two simple mechanisms for the production of 3-A. X-rays in the solar corona: recombination and line emission. Elwert[6] shows that no significant flux is expected from a coronal condensation at 6×10^6 deg. K. on either mechanism. In the case of recombination, the recombining electron must have more than 3 keV. energy, which greatly exceeds the modal energy in the Maxwell–Boltzmann distribution at 6×10^6 deg. K. In the case of line emission, the existence of Fe XXV or Fe XXVI would be required, whereas in the normal corona iron is in the states Fe X–Fe XIV. Since the Sun is able to produce cosmic rays, one cannot rule out the possibility that it also emits 3-A. X-radiation, by some unknown mechanism. The existence of high-temperature regions, at 10^7 deg. K., would produce the required radiation. However, there is no optical evidence for such regions. Another possibility is that 3-A. X-rays are produced locally, in the Earth's atmosphere. The observation[7] of soft radiation in the auroral zone at low elevations supports such a conjecture.

This investigation was supported by the Air Force Cambridge Research Center, Air Research and Development Command.

J. W. WARWICK
H. ZIRIN

High Altitude Observatory,
Boulder, Colorado.

[5] Warwick, J. W., *Astrophys. J.*, 125, 811 (1957)

[6] Elwert, G., *Z. f. Astrophys.*, 41, 67 (1956).

[7] van Allen, J. A., and Kasper, J. H., *Bull. Amer. Phys. Soc.*, (II), 1, 230 (1956).

IN reply to Warwick and Zirin's communication, we wish to comment first on their suggestion that the observed 3-A. X-rays were produced locally, in the Earth's atmosphere. The detector in our experiment is a photon counter mounted on the wall of the cylinder that encloses the instrumentation section of the rocket. The beryllium window of the counter lies almost flush with the surface of the cylinder and looks out in a direction normal to the long axis of the rocket. As the rocket rolls during flight, the photon counter can 'see' the Sun once per roll. During the flight, X-rays were detected only when the photon counter 'saw' the Sun. There can be no question but that the measured radiation came directly from the Sun and not from the Earth's atmosphere.

Any conclusion regarding the increase in *D*-region electron density resulting from the observed X-ray flux depends very much on the assumed values for recombination coefficients at different altitudes. Since submitting our original communication to *Nature*, we have made more detailed analyses of our observations. We estimate the total flux in the 3–8 A. band to have been 5×10^{-3} ergs/cm.^{2}/sec. From the dependence of intensity on altitude we found that the first decade of absorption took place roughly between 98 and 85 km.; the second decade between 85 and 78 km. Very little radiation penetrated below 78 km. Knowing the rate of absorption at any given level, an electron density can be computed if the recombination coefficient is known. Assuming the recombination coefficient α is 10^{-7} cm.^{3}/sec. between 85 and 98 km., we get 3×10^4 electrons/c.c. If α increases to 10^{-6} cm.^{3}/sec. between 78 and 85 km., we obtain about 4×10^3 electrons/c.c. in that range. According to estimates of the normal *D*-region based on radio measurements[1], a density of 3×10^4 per c.c. occurs at about 93 km., and 4×10^3 at 81 km. Hence the X-ray source should have increased the electron density in the *D*-layer by about 40 per cent.

As Warwick and Zirin suggest, the absorption effect is very sensitive to the altitude of the absorbing region (75–80 km.). The major effect of the X-ray ionization certainly occurred well above 80 km. It is not surprising, therefore, that the observed cosmic noise absorption was small and that no fade-out or other form of S.I.D. was observed. We would not expect to see an appreciable lowering of the base of the *D*-layer unless the flare were very much greater. However, because we observed an unusual X-ray increase in such a small flare, it seems plausible to expect much greater X-ray emission accompanying a flare capable of producing an S.I.D.

We hope to obtain the experimental measurements needed to answer the question of the relative importance of Lyman α- and X-rays in S.I.D. phenomena from a series of rockets to be fired during the International Geophysical Year. Beginning July 1, fourteen Nike–Deacon rockets instrumented to measure Lyman α- and X-rays will be ready for firing from San Nicolas Is. in the Pacific Ocean off Point Mugu, California. These rockets will be held in readiness for the occurrence of flares producing S.I.D. Combined with the flare observations on Mt. Wilson, Sacramento Peak and Climax, these measurements should contribute substantially to our understanding of solar flares.

Chemical Mechanism of Permanent Set

ALL available methods of imparting a permanent set to strained wool fibres are based on two consecutive intramolecular reactions, namely, disulphide bond breakdown, which promotes relaxation, and linkage rebuilding, which fixes the relaxed structure in its deformed state. The linkage rebuilding reactions are complex[1], but when a boiling 2 per cent solution of borax is used as the setting agent, one important reaction is that between the sulphenic acid, formed by breakdown of the disulphide bond, and the basic side-chains; set fibres contain fewer free lysine side-chains than untreated fibres[2], and fibres treated with 1-fluoro-2 : 4-dinitrobenzene acquire much less set than untreated fibres[3]. In striking contrast with these observations, it has now been found that the lysine side-chains play little, if any, part in the setting of strained fibres in a boiling solution of sodium bisulphite.

Lincoln wool fibres in the untreated state, after treatment with buffer and after treatment with 1-fluoro-2 : 4-dinitrobenzyl, were stretched 35 per cent, boiled for 30 min. in either a 2 per cent solution of borax or a 5 per cent solution of sodium bisulphite, and then released in boiling water. The amounts of set retained by the fibres after various times of release are shown in Table 1. Fibres treated with 1-fluoro-2 : 4-dinitrobenzene show such a marked contrast between borax and sodium bisulphite as setting agents as to leave no doubt that the main linkage-rebuilding reaction is different in the two cases. This deduction is supported by the fact that there is little difference between the amounts of free lysine side-chains in untreated wool and wool which has been set at 40 per cent extension in a boiling 1 per cent solution of sodium bisulphite for 1 hr. The set fibres were treated with 1-fluoro-2 : 4-dinitrobenzene and then hydrolysed, the ε-*N*-dinitrophenyllysine being isolated from the hydrolysate and estimated colorimetrically[3]. The lysine content of the set fibres was found to be 3·44 per cent, compared with 3·38 per cent for the untreated wool. In the light of these and earlier results[1], it seems clear that the rebuilding of disulphide bonds is the main cross-linking reaction when stretched wool fibres are set by means of a boiling solution of sodium bisulphite.

Table 1

Setting agent	Treatment of fibre	Percentage set after release in boiling water for : 5 min.	30 min.	60 min.
Borax	Untreated	23·3	26·6	26·3
	Buffer	24·1	22·0	21·4
	1-Fluoro-2 : 4-dinitrobenzene	18·6	12·8	11·9
Sod. bisulphite	Untreated	21·7	21·2	21·1
	Buffer	23·2	22·5	22·0
	1-Fluoro-2 : 4-dinitrobenzene	25·5	24·6	24·3

An Approach to the Synthesis of Polycyclic Peptides

ACCORDING to the cyclol hypothesis of peptide structure[1,2], intact peptides may have polycyclic structures which can be visualized, in part at least, as polycyclizations of peptide chains by means of [CO,HN to C(OH)—N] proton transfers. Here the H of the NH group of one residue is transferred to the CO-group of another: a N—C bond forms and the CO-group is replaced by a tertiary carbinol[3]. There result multiple as well as the CO–NH single peptide groupings. Fig. 1 shows some structures which emerge when consideration is confined to (1,6) and (3,7) transfers and piperazine and hydantoin rings are formed.

A molecule containing a multiple peptide or cyclol grouping has been synthesized[4], following the discovery of such a grouping in the peptide moiety of the ergot alkaloids[5]. This communication is concerned with the possible presence of such groupings in other synthetic molecules[4–8].

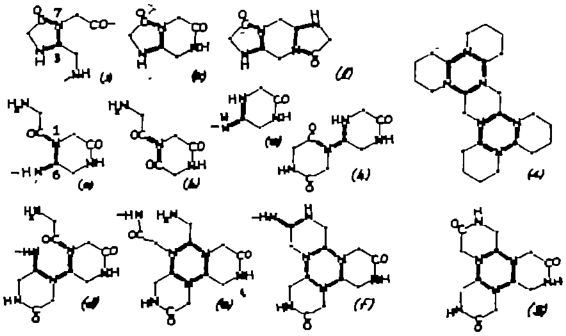

Fig. 1. Cyclized peptide chains, open and closed, in which · denotes CHR and ○ denotes C*(OH), and multiple peptide groupings composed of 2-, 3-, . . . 6-bonds uniting the residues are marked by heavy lines. Polycyclizations leading to cyclol-6 are depicted in (c–g), the structure cyclol-10 in (i). The diagrams indicate that hydrogen bridges would be possible in most cases, and that water molecules may be built in by means of hydrogen bridges, particularly in (i)

The new synthesis, achieved by a transannular interaction [CO,HN—CO to C(OH)—N—CO] across a cyclic keto-amide, shows that under appropriate stereochemical or geometrical conditions "amide bonds can exhibit a chemical reactivity greater than is usually attributed to them"[4], and indicates the impact on the experimental study of the cyclol hypothesis of the knowledge of transannular interactions between CO and NR groups now available[9]. Of signal importance is the fact that this transannular interaction, which changes a more or less flexible 10-atom ring into a rigid bicyclic structure, is spontaneous[4]. How is this to be reconciled with the fact that it replaces a CO-group by a high-energy tertiary carbinol? Presumably sufficient stabilization is conferred on the molecule by the interlocking rings. The case of the ergot tripeptides[3] prompted the same conclusion[2]. Here then are two structures which may be regarded as documents awaiting detailed interpretation. These and others now expected[2] will no doubt point the way to the systematic quantitative evaluation of stabilizing energies from this source, or perhaps to a broader view regarding the analysis of the heat content of molecules in which the multiple connexions between atoms in the structure play a leading part.

Multiple peptide groupings may be present in the recently synthesized hexaglycyl[5-7] and tetraglycyl[7] compounds. The monocyclic, closed peptide chain type of structure which is generally assumed for a peptide which has the composition $nA - n\text{H}_2\text{O}$, where A denotes an amino-acid molecule, is then supplemented by a number of possibilities which also merit consideration. Examples are shown in Fig. 1, (*b,k*) for $n = 3$, (*h,l*) for $n = 4$ and (*g*) for $n = 6$, (*i*) for $n = 10$. Some of these polycyclic structures are of special interest for these two compounds, because of features in the infra-red spectra[7] which so far lack interpretation.

Other findings also remain unexplained. One synthesis of the hexaglycyl compound was by way of an open polyglycine chain[5]. This was obtained by the polymerization of *N*-carboxy glycine anhydride in which, strikingly enough, an intermolecular proton transfer of cyclol type [CO,HN to C(OH)—N] is postulated. But taking the peptide chain structure as given, how is the ring closure to be explained? Why is the predominant product the hexa- and not the penta- or hepta- or other poly-glycyl? However, picturing not only inter- but also intra-molecular cyclol transformations leading to polycyclic structures, somewhat as the transformation of squalene to lanosterol[10,11] is visualized, a polycyclic structure would result, perhaps even cyclol-6, as depicted in (*c–g*). Alternatively, given the closed hexaglycyl chain, we can visualize 1, 2 or 3 separate (3,7) transannular interactions, or three related ones each facilitating the next and resulting in cyclol-6. The hexacyclic structure (*g*) with its kernel of a closed 6-bond multiple peptide binding would presumably have a considerable stability, perhaps increased by a trigonal circuit of OH··O hydrogen bridges or built-in water molecules or both. [The corresponding cyclol-10 structure is also of great interest. It is possible that this structure with its six additional asymmetric carbon atoms, or a partially decyclized form of it, might account for various properties of gramicidin-S so far unexplained (see R. Consden *et al.*, *Biochem. J.*, 41, 596; 1947). This decapeptide, for which two of the residues are assigned D-forms, has a high optical rotation; it is more resistant to hydrolysis than its partial hydrolysis products; these products do not include prolylvaline.] A cyclol-6 structure would explain the most striking 'anomaly' regarding the hexaglycyl, its resistance to acid and alkali hydrolysis. Whether this compound in fact has the closed peptide chain structure which has been assigned to it without discussion, or one or other of the various polycyclic structures, remains to be discovered. In view of the possibility of spontaneous polycyclizations, the tetraglycyl compound may also have a polycyclic structure, (*h*), (*l*), etc. All these issues can be studied also in relation to the unexplained features of the highly interesting infra-red spectra.

In this and other connexions, structures corresponding to (*h*) and (*g*) in which each CO—NH is replaced by CH_2—CH_2 would be of great value: they would permit the study of the multiple peptide bindings in the absence of CO—NH groupings, a matter of prime importance for interpretation of the spectra. They would have the composition of a valerolactam dimer and trimer. Replacing each CO—NH by CH_2—CH_2—CH_2 would give structures with the composition of the recently synthesized caprolactam dimer and trimer[8,12]. The possibility that these materials have polycyclic rather monocyclic structures merits consideration.

Effect of Experimental Biliary Obstruction on the Phagocytic Activity of the Reticulo-Endothelial System

EXPERIMENTAL and clinical studies have frequently been reported on the effect of biliary obstruction and portal cirrhosis on the functions of the liver; but no reports on the influence of these conditions on the reticulo-endothelial system appear to have been recorded. The following investigations were therefore planned to study the effect of experimental biliary obstruction on the phagocytic activity of the reticulo-endothelial system.

The present experiments were carried out on male white rats of about 150 gm. body-weight. In thirty-eight rats the common bile duct was ligated under ether anaesthesia. These animals were then divided into five groups in which the phagocytic activity of the reticulo-endothelial system was measured at 3, 7, 16, 25 and 38 days respectively after the operation. Twenty-two intact males were used as controls. The phagocytic activity was measured by the rate of

Table 1. Shows Effect of Ligation of Common Bile Duct on the Phagocytic Activity of the Reticulo-endothelial System

Duration of biliary obstruction	No. of animals	Average weight gain in gm.	Weight of liver in gm. per 100 gm. of body-weight	Weight of spleen in gm. per 100 gm. of body-weight	Body-weight divided by weight of liver and spleen	Phagocytic index (K value)	Unit activity of reticulo-endothelial tissue (α value)
3 days	6	1	5·7	0·35	16·8	45	5·9
7 days	8	6	6·0	0·41	15·7	58	5·8
16 days	10	2	5·7	0·80	15·4	88	6·6
25 days	8	30	5·5	0·99	15·6	76	6·5
38 days	6	42	4·5	0·69	19·4	41	6·6
Control value in 22 animals			4·0	0·58	22·2	26	6·4

disappearance of a known amount of carbon from the circulating blood[1], since it has been estimated that about 90 per cent of the carbon is removed from the blood by the Kupffer cells of the liver, 3 per cent by the phagocytes of the spleen and the remainder by those of the bone marrow, lymph nodes and connective tissue. Each animal received one intravenous injection of carbon of particle size 250 A., the dose of the carbon being calculated on the basis of 8 mgm. per 100 gm. body-weight. Blood was then taken at short intervals over the period of one hour following the injection, and the concentration of the carbon in each blood sample was recorded by an absorptiometer. The logarithmic values of the absorptiometer readings lie on a straight line when plotted against time, and the slope of the line has been taken as the measure of total body phagocytic activity or the phagocytic index, which is denoted in the present communication by the symbol K. On the other hand, the phagocytic activity per unit of reticulo-endothelial tissue, here denoted by α, has been found to vary for a given dose of carbon according to the following equation[2]:

$$\alpha = \frac{\text{Total body-weight of animal}}{\text{Combined weights of liver and spleen}} \cdot \sqrt[3]{K}$$

All the animals were killed one hour after the carbon injection. In those in which the common bile duct was ligated it was found that the proximal part of the duct had become enormously dilated and contained a yellowish watery fluid. The body-weight and the weight of the liver and spleen were then recorded for each animal, and specimens of liver and spleen were fixed in Heidenhain's Susa fluid. Sections 10µ thick were cut and stained with weak eosin, or by a modified Masson's trichrome technique.

In a further group of ten animals the common bile duct was also ligated. These animals were kept for 42 days after operation, but after the thirty-eighth day they became increasingly ill and had to be killed.

The results are shown in Table 1. The weight of the liver is found to have increased by more than one-quarter by the third day after operation, the increase being maintained to the twenty-fifth day, after which it falls slightly. In the case of the spleen the weight falls during the first week, then rises to nearly double by the twenty-fifth day, after which it falls slightly. These changes are reflected in the ratio between body-weight and the combined weights of liver and spleen.

Following ligation of the common bile duct, the total body phagocytic activity (K value) becomes increased from 26, which is the average in the control animals, to 45 by the third day. The increase continues until the sixteenth day when it has risen to 88. Thereafter there is a gradual fall, although at the thirty-eighth day after operation the phagocytic activity still remains well above normal. In contrast the unit activity (α value) of the reticulo-endothelial tissue remains remarkably constant, which suggests that the increase in total body phagocytic activity (K value) may be due to increase in the amount of reticulo-endothelial tissue.

Microscopically, the liver parenchyma cells show surprisingly little degenerative change although small areas of necrosis may be found. The sinusoids are dilated and a progressive fibrosis develops around the portal vessels and gradually extends into the lobules. The Kupffer cells are filled with carbon; but throughout the groups of animals they show little variation from the controls in regard to number of cells and the amount of carbon phagocytosed, the appearances being in agreement with the relatively constant values of the unit activity of the reticulo-endothelial tissue (α value). In the spleen the capsule and the trabeculae become thickened, the Malpighian bodies less clearly defined and the reticulo-endothelial cells show increased activity as indicated by their number and the amount of carbon phagocytosed.

The above results show that when acute biliary obstruction is maintained an increased activity of the reticulo-endothelial tissue of the liver and spleen rapidly develops and continues for about five weeks, after which the animals become increasingly ill and die. The stimulation of the phagocytic activity may be due to the accumulation in the blood of steroids which are normally excreted or denatured by the liver[3,4]. This would be in agreement with the findings of Nicol *et al.*[5], who showed that natural and synthetic œstrogens stimulate the reticulo-endothelial system.

In these investigations we gratefully acknowledge assistance from the French Government and the CIBA Foundation, which made possible the co-operation between the two Departments.

Effect of Copper and Chelating Agents on Growth Inhibition of *Aspergillus niger* by 8-Hydroxyquinoline and Pyridine-*N*-Oxide-2-Thiol

WHEN examining the toxicity of chelating agents, we have to deal with the toxicity of each of three entities, namely, the chelating agent itself, the unsaturated complex(es) of metal and chelating agent, and the saturated complex; for example, for copper and 8-hydroxyquinoline: free oxine, $CuOX$ and $CuOX_2$. Thus we found[1] for *Aspergillus niger* a minimal growth-inhibitory concentration of 50 p.p.m. for sodium dimethyldithiocarbamate, when the medium was free of heavy metals. The 1 : 2 complex with copper appears to be non-toxic, whereas the 1 : 1 complex is toxic. The activity of the 1 : 1 complex is abolished, however, when copper is removed from this complex by addition of a stronger, non-toxic chelating agent such as sodium dibutyldithiocarbamate.

Growth inhibition by two other chelating agents, namely, oxine (applied as the sulphate) and pyridine-*N*-oxide-2-thiol, and by their copper complexes has now been studied. For these a different pattern of toxicity was observed by Albert and co-workers for bacteria[2,3], and this was confirmed for the fungitoxic action of oxine by Block[4].

Shake cultures were made[5] of *Aspergillus niger* strain *M* in glucose mineral salts solution (*p*H 7·0), prepared with glass-distilled water and analytical grade reagents[1], and incubated for three days at 24°. The growth-inhibitory concentrations of oxine sulphate and pyridine-*N*-oxide-2-thiol were 0·2 and 0·5 p.p.m. respectively. In spite of many precautions, however, this shake medium was not completely free of heavy metals, as addition of 1 p.p.m. or higher concentrations of sodium dibutyldithiocarbamate, a stronger chelating agent than oxine or pyridine-*N*-oxide-2-thiol, decreased toxicity of these compounds to a minimal inhibitory concentration of 10 p.p.m. We assume that heavy metals drained from the glass wall were sufficient to form a toxic complex with oxine or pyridine-*N*-oxide-2-thiol. The copper content of the liquid medium itself was not greater than 0·01 p.p.m. (calculated as $CuSO_4.5H_2O$), as indicated by the yellow spores of *A. niger* strain *M* grown on agar media of the same composition[6].

$CuOX_2$ and the copper pyridine-*N*-oxide-2-thiol complex ($CuPTO_2$) are far more toxic than the chelating substances themselves. We found 0·1 and 0·2 p.p.m. as minimal inhibitory concentrations for these complexes.

Table 1 shows the effect of addition of copper to oxine sulphate and pyridine-*N*-oxide-2-thiol. Toxicity is first slightly increased, but with further increase of the copper concentration (as the 1 : 2 complex turns into the 1 : 1 complex) it decreases gradually. This decrease can be explained if we assume that a similar mechanism operates in *growth-inhibition* of *A. niger* by the copper complexes of oxine and pyridine-*N*-oxide-2-thiol as Albert and co-workers[2,3] have suggested for the *bactericidal* action of the corresponding ferrous iron complexes. The 1 : 1 complex is regarded by these authors as the actual toxic agent, but is supposed to enter the cells only very slowly. The 1 : 2 complex is believed not to be toxic as such, but to penetrate quickly into the cells and then to be transformed into the toxic 1 : 1 complex.

Table 1. EFFECT OF ADDITION OF COPPER SULPHATE ON GROWTH INHIBITION OF *Aspergillus niger* BY OXINE SULPHATE AND PYRIDINE-*N*-OXIDE-2-THIOL

	p.p.m.	Min. inhibiting conc (p.p.m.)	
		Oxine sulphate	Pyridine-*N*-oxide-2-thiol
$CuSO_4.5H_2O$	0	0·2	0·5
	0·03	0·1	0·2
	0·1	0·1	0·2
	0·3	0·1	0·5
	1	0·2	0·5
	3	0·5	0·5
	10	0·5	0·5

It is possible to calculate the approximate amounts of 1 : 2 and 1 : 1 complexes, when copper and oxine are present together, if the solubility of $CuOX_2$ and the equilibrium constant K of the reaction

$$Cu^{++} + CuOX_2 \rightleftharpoons 2\,CuOX^+$$

are known. Log K was determined spectrophotometrically and found to be 0·8.

These calculations were carried out for the culture media, making allowance for the occurrence of $CuOH^+$. $CuOX_2$ is never precipitated in these solutions, since the solubility was found to be about 1 p.p.m. The results (not reproduced here) indicate that, when copper is present in excess, concentrations of $CuOX_2$ exceeding 0·03 p.p.m. are toxic, whereas no correlation is found with the amount of 1 : 1 complex present. This suggests strongly that the concentration of 1 : 2 complex is decisive for toxicity. Only when $CuOX^+$ occurs in amounts equal to or more than 0·5 p.p.m. (namely, in the combination of 0·5 p.p.m. oxine sulphate and 10 p.p.m. $CuSO_4.5H_2O$ where only 0·02 p.p.m. $CuOX_2$ is present) it seems to have a definite effect of its own.

When there is less copper than required to convert all oxine in the medium into $CuOX_2$ (that is, when excess oxine is present) the correlation between toxicity and amount of $CuOX_2$ present does not apply. It seems as if, inside the cells also, an excess of copper must be present in order to transform $CuOX_2$ into $CuOX$ there.

Ferrous sulphate was found less effective than copper sulphate.

Our growth results with oxine agree more or less with those of Block[4] and of Anderson and Swaby[6].

Growth inhibition of *A. niger* by oxine and pyridine-*N*-oxide-2-thiol seems to differ from that effected by sodium dimethyldithiocarbamate in so far as the 1 : 2 complexes of the former are toxic whereas that of the latter is not[1]. The most plausible explanation for this fact is the difference in solubility in water of the three 1 : 2 complexes. These have been estimated to be about 1, 0·2 and 0·01 p.p.m. respectively (unpublished work). Obviously, the toxic concentration for *A. niger* can be reached in aqueous solution by $CuOX_2$ and by $CuPTO_2$ but not by the saturated complex of copper dimethyldithiocarbamate ($CuDDC_2$). So that in the latter case toxicity is determined only by the amount of CuDDC present.

This hypothesis is substantiated by the observation that there are certain more sensitive moulds which are inhibited by the small amounts of $CuDDC_2$ which dissolve. These moulds show in fact an inhibition pattern by sodium dimethyldithiocarbamate and its copper complexes which is so similar to that of oxine and pyridine-*N*-oxide-2-thiol and their complexes that the same principles appear to underly toxicity.

This pattern will be followed in general if the solubility of the 1 : 2 complex exceeds the minimal inhibiting concentration for the organism involved. If the solubility is lower, the pattern of *A. niger* treated with sodium dimethyldithiocarbamate can be expected.

We thank Dr. G. J. M. van der Kerk for his interest in this work, and Dr. Gerretsen, of Groningen, for supplying a culture of *A. niger* strain *M*.

State of Copper in Polyphenoloxidase (Tyrosinase)

IT was shown in the classical work of Kubowitz[1] and of Keilin and Mann[2] that the prosthetic group of polyphenoloxidase is constituted by copper. Since then it has been unanimously admitted that the metal of the enzyme is in the bivalent state and that the catalytic activity of the enzyme is based on the change of valency cupric ⇄ cuprous, as follows (for excellent discussions, see refs. 3,4):

$$\text{(1)}\quad 2\,\text{Cu}^{2+}\text{-enzyme} + o\text{-dihydroxyphenol} = 2\,\text{Cu}^{+}\text{-enzyme} + o\text{-quinone} + 2\text{H}^{+}$$

$$\text{(2)}\quad 2\,\text{Cu}^{+}\text{-enzyme} + \tfrac{1}{2}\text{O}_2 + 2\text{H}^{+} = 2\text{Cu}^{2+}\text{-enzyme} + \text{H}_2\text{O}$$

$$o\text{-dihydroxyphenol} + \tfrac{1}{2}\text{O}_2 = o\text{-quinone} + \text{H}_2\text{O}$$

The substrate is oxidized by losing two electrons and two protons. The two electrons are taken by the copper of the enzyme which thus passes to the cuprous state. The cuprous enzyme rapidly transfers the two electrons to oxygen (which immediately forms water with the two protons liberated) and so returns to the cupric state ready to recommence the catalytic cycle.

This certainly very attractive hypothesis is based on ingenious but indirect evidence. Kubowitz[1] has shown that potato-polyphenoloxidase takes up 0·5 *M* carbon monoxide per mole copper only in the presence of the substrate and that the bound carbon monoxide is liberated again by adding hydrocyanic acid. It must be remembered, however, that this experiment is a difficult one: the low copper content of the enzyme makes the use of a large amount of protein (85 mgm.) for each Warburg flask unavoidable; nevertheless, the pressure differences read on the manometers remain relatively low[5] (11 mm. and 12 mm.). Moreover, the purity of the enzyme used by Kubowitz[1] was only 65 per cent of his best preparation, which appears to have a rather low specific activity[5].

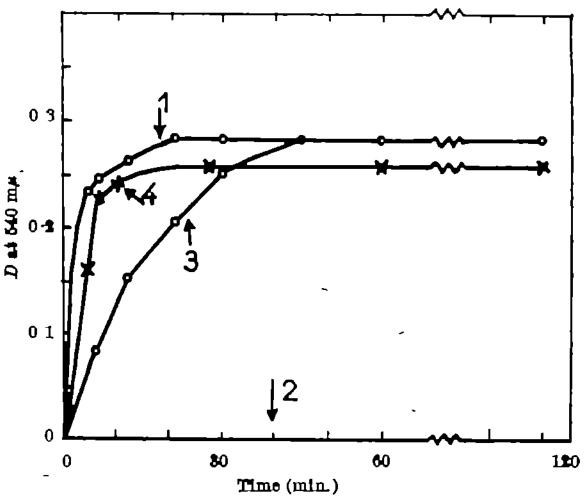

Fig. 1. Course of the reaction between copper and 2.2′-diquinolyl in acetic acid. Curve 1: 11·5 μgm. cuprous ions in 2 ml. 0·05 *M* phosphate buffer pH = 6·8, to which, at zero time, 1 mgm. of 2.2′-diquinolyl in 1 ml. of glacial acetic acid was added. Curve 2: 11·5 μgm. cupric ions in the same buffer and the same reagent. Curve 3: as in curve 2, but at zero time hydroxylamine sulphate (in crystals) was added. Identical results were obtained with copper previously incubated with 5·53 mgm. of bovine serum albumin and with conalbumin. Curve 4: 5·32 mgm. polyphenoloxidase containing 10·6 μgm. copper (as determined by an independent method (ref. 9)) in the same buffer and reagent as in curve 1

The recent preparation of mushroom-polyphenoloxidase which appears homogenous by electrophoresis and by ultracentrifugation[5], and the discovery of a reagent specific for cuprous copper by Hoste[6] has made possible a direct examination of the state of copper and of any valency change during its catalytic activity.

The time course of the reaction of copper with 2.2′-diquinolyl in glacial acetic acid (as measured with a Beckman *DU* spectrophotometer at mμ 540) is shown in Fig. 1. On the addition of the reagent to cuprous copper the characteristic colour appears immediately and after a short period of increase remains stable (curve 1); the later addition of a reducing agent (hydroxylamine sulphate[6]) does not have any influence on the colour. Cupric copper does not react at all (curve 2). If to a solution of cupric copper + 2.2′-diquinolyl in glacial acetic acid a reducing agent is added, the colour develops and stabilizes relatively slowly (curve 3). The same measures were repeated in presence of copper incubated with crystalline bovine serum-albumin and with conalbumin, two proteins which bind copper strongly[7]. The course of the reaction and the value of the absorption remained identical, showing that the glacial acetic acid of the reagent separates the copper efficiently and quantitatively from these proteins[8].

The reaction of polyphenoloxidase with the reagent, in air and in the absence of substrate, is shown by curve 4. The presence of substrate (2, 1, 0·5 and 0·25 *M* catechol per mole copper) in anaerobic conditions under argon or under carbon monoxide and the previous or later addition of a reducing agent have not the least influence on the time course or on the value of the absorption.

It is evident that the copper of the polyphenoloxidase is always in the cuprous state. The alternative explanation of these results, namely, that the copper is reduced to the monovalent state by a hypothetical reducing agent belonging to the apoenzyme after it has been separated from its specific site by the acid of the reagent, is excluded by the time course of the reaction.

Biological Role of Potassium-40

My investigations on the effect of potassium-40 upon the growth and development of *Aspergillus niger* lead to the conclusion that the radioactivity of potassium-40 (normally present in organisms) is not connected with any biological reaction or process proceeding under normal conditions in plants and animals[1]. Direct confirmation by experimental observations on the influence of potassium-40 upon animals was not given.

For this purpose, the isolated heart of a frog has been perfused with physiological Ringer solutions containing: (1) ordinary potassium; (2) potassium enriched in potassium-40; and (3) potassium impoverished in potassium-40.

The isotopic composition of the potassium was the same as that used in my earlier work[1]. The enriched potassium contained 1·34 per cent of potassium-40 and the impoverished 0·0002 per cent of potassium-40. The composition of the physiological Ringer solution was: sodium chloride 0·60, potassium chloride 0·01, calcium chloride 0·01, sodium bicarbonate 0·02 and water 100·0.

The Ringer solution was passed through the sinus venosus and the right aortic arch of the isolated heart of autumn frogs (*Rana ridibunda*). The pulmonary vessels and the left aortic arch were ligatured. The cannulas were joined to the isolated heart apparatus with the aid of thin glass sections. During the experiment the venous and arterial pressures were maintained at constant levels.

The contractions and the amplitudes of the heart action were recorded as usual on a kymograph.

The perfusion solutions were alternated in various combinations: (1) solutions containing ordinary potassium; (2) solutions not containing potassium; (3) solutions containing potassium enriched in potassium-40 and (4) solutions containing potassium impoverished in potassium-40. After each perfusion, the solution in the system was carefully flushed out by the next solution to ensure that the effect observed was due to the last solution only. During the perfusion of the solution with no potassium the heart stopped beating.

Table 1

Perfusion solution	Volume of solution (cm³)	Time of perfusion (min.)	Heart action		Time of restoring the heart action (min.)
			No. of contractions/min.	Amplitude (mm.)	
Ringer	—	4	60	10	
Ringer with potassium-39	54	13	60	10	
Ringer with potassium-40	50	14	37·6	9·6	
Ringer without potassium	15	16·5	Stop for 15 min.		
Ringer with potassium-39	40	16	56·4	10·6	7·5
Ringer without potassium	14	10·5	Stop for 5·5 min.		
Ringer with potassium-40	54·5	17·5	57	11·6	6
Ringer	52	14	53·8	18·0	
Ringer with potassium-39	45	12	52·6	13·0	

Parts of the kymograph records obtained in one set of experiments are given in Fig. 1. Statistical analysis of the experimental results has shown that a successive and repeated change of Ringer solutions with an equal content of potassium-40 does not change either the number of the heart contractions or the contraction amplitude.

The results of another experiment are given in Table 1.

The character of the heart muscle contraction depended only on the concentration of the total potassium and did not depend on the content of potassium-40 in it, although the range of the potassium-40 content was changing by approximately 6,700 times.

Direct proportionality between the concentration of the total potassium and the growth of *Aspergillus niger* or the action of the heart muscle was found in all the experiments. There is no such relation between the content of potassium-40 in the potassium of the

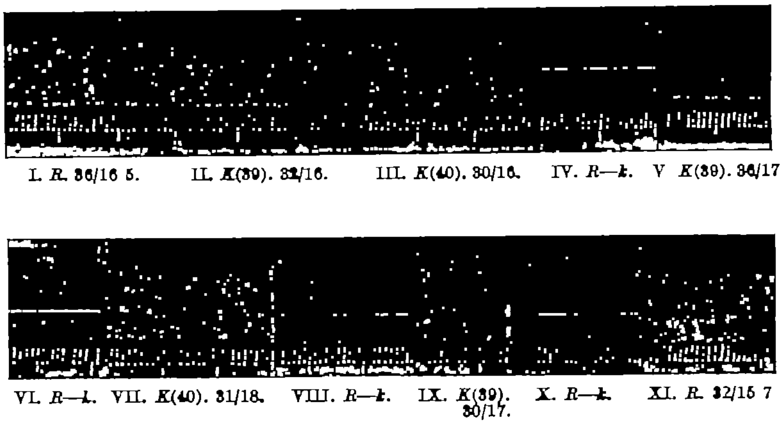

Fig. 1. Kymograph record of frog's heart perfused with various solutions. *R*, Ringer solution with ordinary potassium; *R*—*k*, Ringer solution without potassium; *K*(39), Ringer solution with potassium-39; *K*(40), Ringer solution with potassium-40. The numerals 36/16·5 . . . give the average number of heart contractions in 1 min. followed by the average amplitude of contractions in mm.

Ringer solution (that is, the isotopic potassium composition) and the growth of *Aspergillus niger* or the heart action. Thus the biological role of potassium seems to be related only to its chemical properties and its concentration. As to the radioactivity of potassium-40 (and probably the radioactivity of all the other naturally radioactive chemical elements) normally occurring in all organisms, in the process of phylogenesis the organisms do not appear to have made biological use of the natural radioactivity. Consequently, the radioactivity of potassium-40 does not affect any of the normal biological reactions or processes in organisms; in other words, organisms do not need the radioactivity of potassium-40. The possibility may even be imagined of the existence of a living organism using only potassium-39 completely free of potassium-40. Nevertheless, the tissues of organisms have evidently got a certain resistance against increase in potassium-40 in the medium and against its radiation. With heavy doses of potassium-40, the reaction of organisms is only of a pathological, destructive, negative character.

Resistance of 9-α-Fluoro-11-β-Hydroxyprogesterone to Inactivation in the Liver of the Guinea Pig

THE property of 11-β-hydroxyprogesterone in preventing œstrogen-induced fibroids or œstrogen-induced uterine growth is greatly enhanced[1] by introduction of fluorine at C(9) (Fig. 1); the same applies to the antiluteinizing potency (unpublished work). The antiœstrogenic potencies of the halogenated 11-β-hydroxy compound are possibly even greater than those of progesterone.

The question is which physiological mechanism effects this increase of potency?

Progesterone has long been known to be inactivated in the liver; an amount of progesterone which prevents œstrogen-induced fibroids when absorbed from a subcutaneously implanted pellet loses this property when absorbed from a pellet implanted into the spleen[3] (summary, ref. 4). Thus the question arose whether the considerable increase of the antifibromatogenic and other antiœstrogenic potencies of the halogenated compound may be explained by a greater resistance to intrahepatic inactivation in comparison with progesterone.

Pellets containing 20 or 40 per cent of 9-α-fluoro-11-β-hydroxyprogesterone mixed with 80 or 60 per cent of cholesterol were implanted into the spleen of castrated female guinea pigs. Pellets of œstradiol were implanted subcutaneously. The animals were killed and examined three months later. Results are summarized in Table 1; they should be compared with those in Table 1 of our former communication[1] with subcutaneously implanted pellets of the halogenated compound.

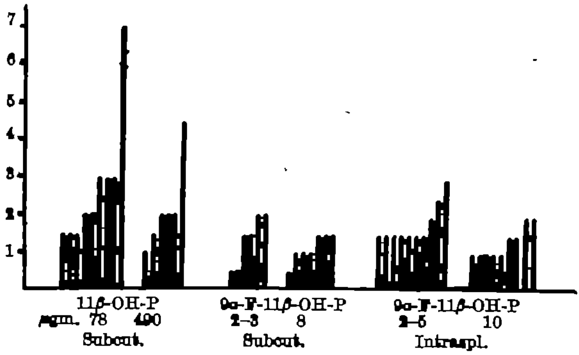

Fig. 1. Comparative antifibromatogenic action obtained with 11-β-hydroxyprogesterone and 9-α-fluoro-11-β-hydroxyprogesterone. Each column corresponds to one animal of the respective group; height of the column-units of our scale of classification of the fibrous tumoral effect[3]. The antifibromatogenic action was greater with 2–8 μgm. of the halogenated compound than with 490 μgm. of the non-halogenated one[1]. Little is changed when the halogenated compound is absorbed from an intrasplenic pellet instead of a subcutaneous one

The halogenated compound is active even when absorbed from a pellet implanted into the spleen (Fig. 1). With such small quantities as 3–10 μgm. a day absorbed from an intrasplenic pellet a very pronounced antifibromatogenic and antihysterotrophic action was manifest, only slightly inferior to that with a subcutaneous pellet of the same compound. Instead of an average fibrous tumoral effect of 4 or more, as obtained in experiments with œstradiol alone, averages of 1·8 and 1·3 were obtained when the halogenated compound was absorbed from an intrasplenic 20 or 40 per cent pellet. Even when making an ample allowance for those great variations which occur in similar experiments with the production and prevention of abdominal tumours, the conclusion is justified that the greater part of the halogenated compound reaches the general circulation without being inactivated in the liver.

A detailed comparison with our former experiments with pellets of progesterone implanted into the spleen is very impressive. Whereas such small quantities as 3–10 μgm. of the halogenated progesterone derivative pass through the liver almost entirely without alteration (Fig. 1), quantities of progesterone as large as ten or even thirty times that are completely, or almost completely, metabolized by the liver (see Group III*a*, ref. 2).

Besides the antifibromatogenic and antihysterotrophic actions, other properties characteristic of progesterone also were manifest in the present work

Table 1. EXPERIMENTS ON NINETEEN CASTRATED FEMALE GUINEA PIGS RECEIVING DURING THREE MONTHS ŒSTRADIOL ABSORBED FROM SUBCUTANEOUSLY IMPLANTED PELLETS, AND 9-α-FLUORO-11-β-HYDROXYPROGESTERONE ABSORBED FROM PELLETS IMPLANTED INTO THE SPLEEN

Group	No. of animals	Œstradiol (μgm./day)	9-α-Fluoro-11-β-hydroxyprogesterone (μgm./day)	Fibrous tumoral effect (average)§	Coeff. Q_{s-t}‡	Uterine weight (gm.)	No. of pellets and concentration of 9-α-fluoro-11-β-hydroxyprogesterone
A	10	45*–87 (55)	3·4 (1–5)	1·8	0·1	1·9 (1·0–3·1)	1 : 20 per cent
B	9	32†–80 (51)	10·0 (7‡–18)	1·3	0	1·8 (0·9–2·9)	1 : 40 per cent

with intrasplenic pellets of the halogenated progesterone derivative. Thus the vagina, which opens under the action of œstrogen, was found closed in eighteen out of nineteen animals; the symphysis pubis opened in five out of nine animals in group *A*, and in eight out of nine animals of group *B*.

There is one objection against the conclusion that the fluoro derivative resists inactivation in the liver. In six out of nineteen animals of groups *A* and *B* there were considerable adhesions between the spleen and the abdominal wall. The question of adhesions in similar experiments has been already discussed on former occasions[4]. It is not likely that results have been stultified by the adhesions.

Thanks are due to Dr. Josef Fried, of the Squibb Institute for Medical Research, New Brunswick, N.J., for 9-α-fluoro-11-β-hydroxyprogesterone; and to Dr. E. Mardones for assistance in examining the experimental animals.

Influence of Hexanitrodiphenylamine on the Incidence of Neoplasms in the Mammary Tissue of Rats

The industrial use of hexanitrodiphenylamine (dipicrylamine, DPA) and the consequent exposure of human beings to it led us to study the chronic toxicity of this compound in experimental animals. In the first part of a feeding test with rats, the substance appeared to have a low toxicity; but towards the end of the life-span of animals which were fed with large amounts of hexanitrodiphenylamine, we were surprised to see that all the females had big and often multiple mammary tumours. These were fibroadenomata, adenofibromata or fibromata of the same type as occur spontaneously in our rats.

In a following experiment, hexanitrodiphenylamine was given to rats, directly after weaning, in a dose of 500 p.p.m., mixed into the dry food. The diet consisted of two-thirds whole wheat meal, one-third of whole dried milk powder and 1 per cent of a salt mixture. Food and water were given *ad libitum*; green fodder twice a week was included. The rats were derived originally from the Wistar strain, but brother–sister mating has not been continued during the past ten years.

Since hexanitrodiphenylamine can easily be hydrolysed *in vitro* to picric acid and picramide (2,4,6 trinitroaniline), these substances were included in the test, using the same dosage of 500 p.p.m. At the end of about two and a half years, the experiment had to be terminated. In the male animals, at autopsy, a variety of tumours were observed. Since neither incidence nor type of these was different from the usual, these animals will not be considered further. In the females, the occurrence of tumours of the mammary glands in the different groups is summarized in Table 1.

Table 1. Incidence of Mammary Tumours in Female Rats treated with Hexanitrodiphenylamine.

Dosage, 500 p.p.m. mixed in dry food. The numbers in brackets indicate total incidence as found in our untreated rats, including that from other experiments during the same period; see text

Group	No. of rats	No. alive after 2 years	No. with mammary tumours	Average age of appearance of tumours
Controls	19 (83)	12 (63)	8 (18)	25 months (26)
Hexanitro-diphenylamine	10	1	10	19 months
Picric acid	10	7	4	22 months
Picramide	8	7	4	20 months

From these observations it appears that in all groups the incidence of mammary tumours is high. Since in the control rats the frequency is much higher than we are accustomed to see, we have included (in brackets) the corresponding data from other untreated control rats, collected from a series of different toxicity experiments in this laboratory with the same kind of rats and diet and from the same period.

Again, in this experiment, every female rat treated with hexanitrodiphenylamine developed mammary tumours, which were found at autopsy, on the average at the age of nineteen months, which is equal to the life-span. In the control rats the age of the appearance of tumours is twenty-five to twenty-six months, and the average life-span more than twenty-five months (nearly half the animals were still alive at the end of the experiment). Without exception all these tumours, including those of the untreated animals, were fibroadenomata, adenofibromata or fibromata. All transplantation experiments with these tumours gave negative results. Another interesting feature is that the rats treated with hexanitrodiphenylamine nearly all had multiple tumours, with an average of three per animal. In control rats the development of more than one mammary tumour in the same animal is seldom observed. Hence this substance seems to increase the rate of formation of this type of tumour in our rats to the level of 100 per cent. Since the spontaneous occurrence is already rather high, it is doubtful whether hexanitrodiphenylamine should be considered on this evidence to be a true carcinogen. In another feeding test, but with mice (F_1 generation of *DBAf* × 0 20) and the same dosage (500 p.p.m.) no effect has been observed within a period of 21 months. This experiment is still going on.

In the case of picric acid and picramide, the incidence of mammary tumours did not differ from the control animals. It seems, therefore, that these products are not responsible for the effect observed with hexanitrodiphenylamine. Rats treated with high dosages of hexanitrodiphenylamine soon develop a purple-brown discoloration of nearly all tissues, and especially of the testis. This effect was not observed with either picric acid or picramide. The composition of the pigment responsible for the discoloration is now being examined.

Copulation in Calanoid Copepods

In the course of picking out copepods for experiments on their feeding, respiration and other activities, I have made a number of incidental observations on the manner of pairing in four species of calanoids (*Centropages hamatus*, *Temora longicornis*, *Eurytemora velox* and *Acartia clausi*), which so far as I know has previously been described in only one calanoid genus, *Diaptomus*[1].

In all these species the process of pairing and the transfer of the spermatophore are substantially the same. Whether the male actively pursued the female could not be determined; the first event in the pairing which was observed was the seizing of the female by the male. This was done by the same means and in nearly the same position on every occasion when it was observed. The male held the female around the terminal segment of the urosome or the caudal rami by means of the right geniculate antennule, the distal part of which was so far reflected that its terminal segments crossed the middle region of the antennule. A pair of copepods might remain for several minutes in this position, and two specimens of *Eurytemora* remained paired in this position for several days in a watch-glass. As the pair swam about, the female made vigorous efforts to shake off the grip of the male and often succeeded. For his part, the male attempted to exchange his first grip for a second in which he gripped the female either immediately in front of, or immediately behind, the genital somite by means of the fifth leg or legs (figures of the fifth legs of these species are given by Sars[2] and Gurney[3]). In most pairs the two animals were lying head to tail with their ventral sides opposed, but in one pair of *Centropages* both had their dorsal sides uppermost and their urosomes so flexed that the genital somites were opposed. *Centropages* habitually holds its urosome dorsally flexed, so that this is a more natural position for copulation in this genus than might at first appear. Since the animals often 'danced' violently in this phase of pairing, it was sometimes difficult to make out the exact position in which they were lying.

It was very easy to determine whether or not a spermatophore had been transferred after the pair had separated, since the spermatophore attached to the genital somite is easily seen; but the actual transfer was never observed. Sars[2] says of *Euchaeta*, and Wolf[1] of *Diaptomus*, that the spermatophore is placed on the genital somite of the female by the left fifth foot of the male. I found some preserved males of *Euchaeta norvegica* in which the minute forceps at the tip of this leg was fixed holding the neck of a spermatophore, but I was unable to determine whether a forceps of this kind was used in the species I observed.

Females examined after copulation had only a single spermatophore attached to the genital somite, and usually the pair separated after this second stage of copulation. In a few cases, however, after transfer of the spermatophore the male reverted to his first grip, holding the urosome of the female with his antennule. Although it was never actually seen, it is possible that a male might clasp the female again with the fifth leg and transfer a second spermatophore—three or four are occasionally found on one female.

The species in which pairing has been described belong to widely separated families of the Calanoida[2,3], but the course of events in pairing is identical in all of them. It seems reasonable to infer that pairing follows very much the same course in all the calanoids which have geniculate antennules and clasping fifth legs, that is, in twelve of the twenty-six families into which Gurney[3] divided the Calanoida. In most of the remaining families the fifth legs clearly form a clasper which, like that of *Euchaeta*, is used in the way suggested above, but the antennule is not geniculate and we have no information about the first phase of copulation.

The observations described were made in the Zoology Department, University of Southampton, and in the Marine Station, Millport.

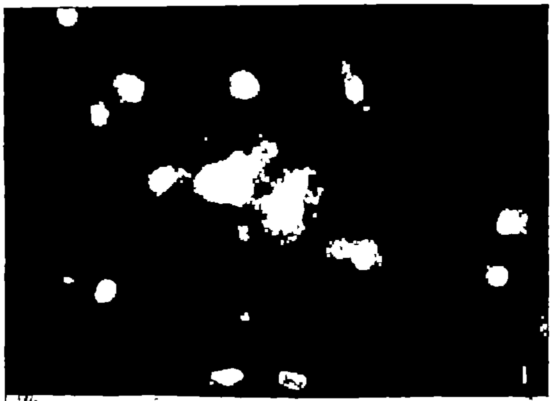
Growth of Fowl Plague Virus in Macrophages and Giant Cells

The fowl plague virus strain 'Rostock' has been grown in monolayer tissue cultures of macrophages. The virus grows rapidly in these cells, producing characteristic cytopathogenic effects.

The macrophage tissue cultures were prepared from heparinized whole chicken blood which was centrifuged to isolate the white blood cells. After 18–24 hr. incubation the cultures are thoroughly washed with Earle's saline, which removes any remaining red blood cells since only the leucocytes firmly adhere to the glass. The nutrient medium throughout this work consisted of 20 per cent chicken serum, 5 per cent embryo extract, and 75 per cent Earle's saline. The Earle's saline was buffered to maintain a pH in the carbon dioxide incubator between 6·5 and 7·0.

The growth of fowl plague virus on 4–5-day old macrophage monolayers has been studied by measuring the release of new infectious particles into the medium, the infectious units being assayed by the Dulbecco plaque technique on chick embryo fibroblasts[1]. After a latent period varying between 1 and 2 hr., there is an exponential release of virus which lasts between 3 and 4 hr. The cells are drastically altered during this time. Already after 1 hr. they cannot be stained by the vital dye, neutral red. Between 6 and 8 hr. after the start of infection, practically all the cells have rounded up and are destroyed.



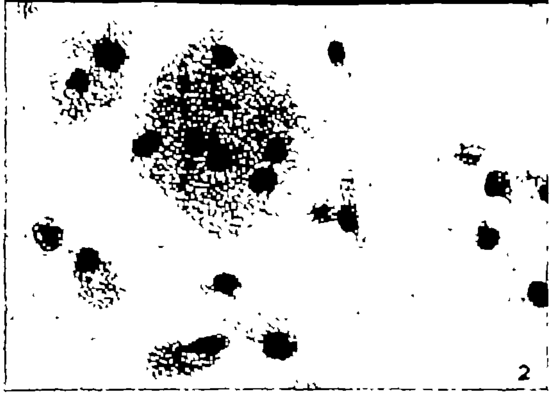


Fig. 1. Macrophage culture 2–3 hr. after infection, fixed in alcohol at – 50° C. and stained with fluorescent antibody to g-antigen

Fig. 2. The same culture stained by the Wright–Giemsa technique

Fluorescent-labelled antiserum to "gebundenes Antigen" (g-antigen)[2,3], the viral component containing all of the ribonucleic acid as well as some of the protein, would be expected to react with closely related components in the infected cell, namely, the soluble antigen (s-antigen)[3,4]. Fluorescein-labelled antibody to g-antigen was used according to the Coons's technique[5], and showed that between 1 and 2 hr. after the start of infection a detectable amount of new s-antigen is concentrated in or around the nucleus. This is similar to the picture obtained by Breitenfeld when the fowl plague virus is grown on monolayers of chick embryo fibroblasts[6] and is also related to the localization of influenza s-antigen in the nuclei of cells of the respiratory epithelium of infected ferrets[7].

Particular attention was focused on the giant cells which typically arise in our macrophage cultures. Giant cells infected with fowl plague can still be stained with neutral red up to 4–5 hr. after the start of infection, but they present the typical picture described above when treated with the fluorescent antibody. Indeed, in the multinucleated giant cells all the nuclei fluoresce. This is illustrated in Fig. 1, which shows an infected macrophage culture containing a giant cell, a young giant cell (dinucleate) and several normal macrophages. Fig. 2, showing the same cells stained with the Wright–Giemsa stain, demonstrates the identity of nuclei and centres of s-antigen localization.

Fowl plague virus multiplies in the macrophage cultures in a virulent fashion. This means a rapid production of new virus with an accompanying cytopathogenic effect, similar to the growth in chick embryo fibroblasts. Recent observations of Barski[8] suggest that the polio virus, Mahoney type I strain, multiplies in tissue cultures of monkey macrophages without the typical cytopathogenic effects which characterize the multiplication of polio on monkey epithelial cells[9]. Furthermore, the polio virus continues to be released from the macrophage cultures as long as eight days after the start of infection, whereas polio virus grown in monkey epithelial cultures is released during a period lasting 4–8 hr. after infection[10]. Thus the macrophage cell can react with virus to produce a 'virulent' type of infection in which the virus multiplies rapidly, or a 'latent' type of infection with a slow and continuous viral growth.

Details of these investigations will be published elsewhere.

The work was carried out during the tenure of a research fellowship from the Fulbright Commission. I am indebted to Dr. P. M. Breitenfeld for the fluorescein-labelled antibody and for instruction in the fluorescent antibody technique. I also wish to thank Dr. W. Schäfer for generous guidance and hospitality.

Honey Bees in Southern Nigeria

THE recent paper by Dr. M. Lindauer on swarm-bees searching for a new home[1] leads me to record some observations on honey bees (*Apis mellifica* L., var. *adansoni* × var. *unicolor*) in the forest region of southern Nigeria which suggest that honey bees there have a preference distinctly different from European bees for their nesting site.

A swarm was placed temporarily in an old box made from 3-mm. plywood which was put on a large lawn in the shade of a dense tree, but exposed to all winds. Twice the swarm flew out and was brought in again. When it was brought in for the third time, the front of the 'hive' was removed and now the swarm stayed, producing and partly filling 10 dm.^{2} of honeycomb in three days. The swarm was then transferred to a proper hive, which it left next morning. The rear end of the inner top cover was then removed, thus letting a draught through the entire hive; the swarm was brought in again the same evening and it now accepted the hive.

Six wild nests of honey bees have been observed. Five of them were in hollow trees, and in each of them the cavity was chimney-shaped, open at both ends with the combs in the lowermost part. Three of these trees were on large clearings exposed to winds from all directions and the nests were placed 2–5 m. above the ground. The other two were in high bush with rather dense undergrowth, and were

15–20 m. above the ground, where the crowns were relatively open. In all these nests the entrance was shaded by the foliage overhead, but there was no (or in one case a very little) foliage in front of them. One nest was inhabited for two and a half years, but when a strangler fig grew up along the trunk and hid the entrance behind dense foliage the nest was abandoned. All these trunks abounded with ants of various species, but evidently this did not cause the bees any inconvenience. The sixth wild nest was situated under the roof of a three-story building, just inside the eaves, the combs hanging down from the roofing sheets (corrugated asbestos cement), the entrance exposed to all winds and the roof baked by the sun during the whole of the day, the inside of the roofing sheets often reaching temperatures above 40° C. There is, however, a steady, fairly strong draught from the eaves towards the ridge. The solidifying point of the wax from this nest proved to be slightly higher than that normally quoted[2], namely, 60·5–62° C.

Wax from uppermost cm. of three oldest combs	63·0°–64·5° C
Wax from uppermost cm. of three youngest combs	63·5°–65·0° C.
Wax from lower parts of three oldest combs	61·8°–62·5° C.
Wax from lower parts of three youngest combs	62·7°–63·5° C
Commercial Beeswax, white (B.D.H.)	60·7°–61·8° C.

In contrast to the preference of the European honey bees for a site sheltered from all winds and for a confined space, the south Nigerian honey bees seem to prefer a site exposed to the winds, and natural ventilation through the nest seems to be essential. I have never observed any preference for wind-exposed sites or for rooms with draught through them by any of the other social bees in this country. It would be most interesting to have further observations from other parts of the tropics.

Right-Ventricle Pressures and Heart-Rate in Diving Birds

FOR these experiments the following sea-birds and water-fowls were used: shag, razorbill, guillemot, black guillemot, puffin and eider. The birds were caught in the bird colonies on oceanic cliffs at Runde, near Aalesund, on the west coast of Norway.

For electrocardiograms, an 'Elema Junior' cardiograph fitted with special electrodes, adapted for this purpose, were used. The electrodes were applied to the left thigh and right side of the thorax. The ventricle pressures were measured electrically by way of a condenser manometer connected to a Tybjerg–Hansen amplifier leading to the electrocardiograph.

Table 1. HEART-BEATS/SEC. BEFORE, DURING AND AFTER DIVING

Species	Heart-beats/sec. Before dive	During dive	After dive	Percentage decrease during dive	No. of exp. birds (and readings taken)
Puffin	7·3	3·0	8·4	59	20 (39)
Guillemot	4·5	1·8	5·6	60	15 (28)
Shag	3·1	1·25	2·9	60	10 (18)
Eider	2·8	1·3	3·1	53·5	2 (4)
Razorbill	3·7	1·4	5·3	62	2 (4)
Black guillemot	5·7	3·3	6·2	42	2 (4)

On the left side of the neck the vena jugularis was freed and 20 mm. of it ligatured. The vein was incised, a catheter connected to the apparatus mentioned was introduced, the heart-side ligature removed, and the catheter pushed by way of the vein into the right side of the heart. The proper application of the catheter was controlled on an X-ray screen. Catheter and vein were sewed together, the catheter fixed to the skin by a few stitches and the wound sutured. During operation the bird was lying on its right side on the operating table, the X-ray unit being below the table.

Thus prepared for experiment, the bird was placed in a basin of water upon a board so that the heart was on a level with the manometer zero-line. Diving was simulated by forcing the head of the bird under water for about 30 sec., registration taking place from the very beginning of diving, or at least from the middle of this period. In all, three periods were registered: (1) immediately before diving, (2) during diving, and (3) immediately after diving. The experimental sequence was repeated after an interval of 2–3 min. Before each of the three steps of experiment, the zero-line and the adjusting pressure (usually 500 mm. water) were measured.

Table 1 shows the heart-beats/second before, during and after diving for 51 birds examined. As will be seen, the mean decrease in heart-rate during diving is more than 50 per cent (except in the black guillemot) and mostly about 60 per cent. The highest normal rate before diving was found in the puffin, and the lowest in the eider. Thus there seems to be an inverse proportionality between heart-rate and body-size. Medium-size birds showed heart-rates between these limits. Shags and eiders are about the same size and have the same heart-rate. The rate after diving is somewhat higher than before diving.

Table 2 shows the results from the pressure experiments. Diastolic and systolic pressures were also measured before, during and after diving, and the stroke pressures in the corresponding periods were calculated. These pressures seem to be nearly the same before, during and after diving. There seems further to be some relation between heart-pressure

Table 2. DIASTOLIC AND SYSTOLIC PRESSURE IN RIGHT VENTRICLE BEFORE, DURING AND AFTER DIVING. THE PRESSURES ARE GIVEN IN MM. WATER

Species	Diastolic pressure Before dive	During dive	After dive	Systolic pressure Before dive	During dive	After dive	Stroke pressure Before dive	During dive	After dive	No. of exp. birds (and readings taken)
Puffin	130	105	126	356	370	360	242	264	239	3 (26)
Guillemot	119	147	102	327	360	366	208	212	246	7 (49)
Black guillemot	85	91	115	288	315	278	203	224	163	3 (25)
Shag	335	348	325	598	640	578	246	289	254	13 (98)

and body-size, the diastolic pressure of the shag being nearly as high as the systolic pressure in the smaller birds. There is no increase in pressures after diving in the birds examined (except diastolic pressure in the black guillemot).

Considering the relation heart-pressure/heart-rate, as appears from Tables 1 and 2, there is no decrease at all in the heart-pressure during diving, although the heart-rate is reduced to about 60 per cent of that before diving. I may also direct attention to the fact that the slightly increased heart-rate after diving (compared with the rate before diving) does not affect the heart pressure at all. The unchanged venous heart-pressures during the three periods referred to suggest that the blood supply to the tissues during diving is kept on the same level as in the non-diving condition. Measurements of the pressures in the arterial heart and the arteries may provide further evidence on how—and where—the regulation takes place.

A full account of this work will appear elsewhere.

Late-glacial Finds of *Lepidurus arcticus* (Pallas) in the British Isles

IN 1894 Bennie[1] recorded abundant remains of this notostracan in association with arctic plant fossils at several localities near Edinburgh in deposits almost certainly of late-glacial age. He[2] found further specimens at Kirkmichael and near Ballaugh in the Isle of Man. There are also old records from Denmark and Sweden[3]. Many late-glacial deposits have been investigated in north-west Europe in recent years, but *Lepidurus arcticus* has not been found.

I am re-examining the Isle of Man deposits, and have made a special search for this fossil. Washings of full-glacial[4] age from Kirkmichael and of late-glacial (*sensu stricto*) age from near Ballaugh both yielded mandibles which were clearly those of a notostracan. As mandibles were common in the Ballaugh material at a stratigraphical level where Zone II was giving way to Zone III, further samples from that level were washed. Carapace fragments with sulcal spines, apodous segments and telsons with short supra-anal plates (Fig. 1) were found. This type of telson is characteristic of *Lepidurus arcticus* (Pallas)[5]. The fossil material is quite diaphanous, and easily escapes observation unless specially looked for. I sieved the samples with a U.S. 40 sieve. I then placed an aqueous suspension of the material retained on the sieve on a white plate, and inspected it in strong light with the aid of a 7× binocular dissecting microscope.

The same stratigraphical level is exposed in a late-glacial deposit at Neasham, Co. Durham[6], and samples from this deposit yielded notostracan mandibles, carapace fragments and apodous segments, but I did not find any telsons. Samples from Zone III at Mapastown, Co. Louth[7], yielded the same fossils. Re-examination of samples from other late-glacial localities would undoubtedly add many further identifications.

It is thus clear that *Lepidurus arcticus* was widely distributed in the British Isles in late-glacial time.

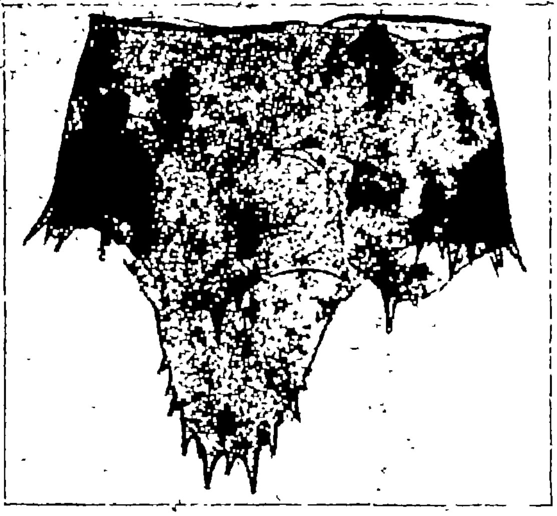

Fig. 1. Fossil telson with supra-anal plate of *Lepidurus arcticus* (Pallas): locality, near Ballaugh, Isle of Man; age, late-glacial, Zone II/III. × 50

To-day[8] there is a relict population in deep lakes in the Scandinavian mountains, where it descends to 58° N.; it descends to 57° N. in the Priblyoff Islands. But the main distribution is circum-polar, between 65° and 80° N., where it occurs in ponds and around shallow lake-margins, and is often very abundant. The late-glacial habitats must have been very similar.

Chirality

THE recent work on particle parity stresses the need for a suitable term for the property characterizing those three-dimensional forms which are distinct from their mirror-images. 'Spirality', even if understood in the sense of a helix, is misleading, since many forms possess a non-superimposable mirror image but no helical axis; for example, scalene spherical triangles, isosceles tetrahedra with scalene faces, and certain types of optically active molecule. Kelvin[1], Larmor[2] and Eddington[3] have used the term 'chirality', from χειρ, hand. Chiral structures or fields are those which exist in two distinct mirror image forms, while non-chiral forms are single, possessing either a centre or a plane of symmetry.

FORTHCOMING EVENTS

Sunday, September 8—Wednesday, September 11

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Dublin).—Continuation of Annual Meeting.

Sunday, September 8

At 11.15 a.m.—(in St. Patrick's Cathedral)—Religious Service. Preacher: The Lord Archbishop of Dublin.

Monday, September 9

At 10 a.m.—Dr. G. H. Mitchell, F.R.S.: "Ordovician Volcanoes" (Presidential Address, Section C).

At 8 p.m.—Sir Sydney Caine: "Education for Development".

Friday, September 13

ROYAL AERONAUTICAL SOCIETY (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6 p.m.—Dr. Clark B. Millikan (California Institute of Technology): "Advanced Education and Academic Research in Aeronautics" (45th Wilbur Wright Memorial Lecture).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

SCIENTIST (with an honours degree, or equivalent qualification, in chemistry or physics, preferably with experience in the coalmining industry and with wide analytical experience and administrative ability) as assistant to the Area Chief Scientist in the North Staffordshire Area Laboratory, Stoke on Trent—Area Staff Manager, West Midlands Divisional Coal Board, 72 Leek Road, Stoke-on-Trent (September 18).

TECHNICAL ASSISTANT (preferably with some knowledge of photographic techniques) IN THE DEPARTMENT OF BOTANY, University of Natal, Pietermaritzburg—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, September 15).

CHIEF TECHNICIAN IN THE DEPARTMENT OF ZOOLOGY, University College of Ghana—The Assistant Registrar (London), University College of Ghana, 29 Tavistock Square, London, W.C.1 (September 16).

SCIENTIFIC OFFICER (with an honours degree in agriculture or agricultural botany, or equivalent qualification, with a sound knowledge of the principles of genetics and practical plant breeding, preferably with experience in design and analysis of field trials) IN THE PLANT BREEDING DIVISION, Ministry of Agriculture, Loughall, Co. Armagh—The Secretary, Civil Service Commission, Stormont, Belfast (September 18).

PRINCIPAL (with a degree in engineering, or professional equivalent, with technical college teaching and administrative experience, also some industrial experience) OF A NEW TECHNICAL INSTITUTE, Ibadan, to administer, organize and assist in the establishment of a new Institute, and to correlate administration of technical institute with trade training centre—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting BCD.114/410/016 (September 27).

PROFESSOR (with a university degree in science or agriculture, with special qualifications and experience in teaching and research) OF PLANT SCIENCE (AGRICULTURAL BOTANY) at the Canterbury Agricultural College, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (September 30).

LECTURER, Grade I or II, IN LOW TEMPERATURE PHYSICS, to give instruction in physics and to lead the low temperature research group under the direction of the Professors of Physics—The Registrar, The University, Bristol 8 (October 1).

LECTURER or ASSISTANT LECTURER IN THE RHEUMATISM RESEARCH CENTRE, Clinical Section—The Registrar, The University, Manchester 13 (October 1).

LECTURER and ASSISTANT LECTURER IN PSYCHOLOGY—The Registrar, The University, Hull (October 7).

INSTRUCTOR or ASSISTANT PROFESSOR (with Ph.D. degree, or equivalent qualification, and some university teaching experience) IN ENTOMOLOGY—Prof. I. McT. Cowan, Department of Zoology, University of British Columbia, Vancouver 8, B.C., Canada.

MATHEMATICIAN (with a university degree and preferably some experience of statistics), for work initially concerned with the statistical analysis of data relating to the structural strength and performance of ships, and later with more general problems in the fields of strength, vibration and hydrodynamics—The British Shipbuilding Research Association, 5 Chesterfield Gardens, Curzon Street, London, W.1

RESEARCH ASSISTANT (with a first- or second-class honours degree in biochemistry, or in chemistry and physiology) IN THE PHARMACOLOGY DEPARTMENT—The Secretary, St. Mary's Hospital Medical School, Paddington, London, W.2.

SENIOR LECTURER IN ANIMAL HUSBANDRY at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

SYSTEMATIC BOTANIST (with D.Sc. or Ph.D. degree in botany, preferably systematic botany, and a knowledge and experience of subtropical plants) with the Commonwealth Relations Office for a post in Pakistan. Duties include research work in establishing a national herbarium for the preparation of flora of Pakistan, outlining work on ecological, physiological medicinal plants aspects, also genetics, to be responsible for related work in the Pakistan Forest Research Institute and to act as consultant in organization of research and teaching in botany, possibly also to assist in training of personnel and teaching—The Ministry of Labour and National Service (E.9), Almack House, King Street, London, S.W.1, quoting A.12/PAK/TCS/322.

DEKATRON COUPLING
is best done by the

GTE175M

The GTE175M is a cold-cathode trigger tube specially designed as a coupling element between two Dekatron stages. The employment of an uncoated pure metal cathode ensures a life in excess of 10,000 hrs. Its unique construction is such that a visual indication is given when the valve is conducting. This facilitates rapid checking of the circuit. Power dissipation is at a minimum—the standby condition may be as little as ¼% of that required by hot-cathode tubes under similar conditions.

Life in excess of 10,000 hours
Visual indication when conducting
Low stand-by current
Inexpensive and reliable

COURSES FOR DEGREES OF THE UNIVERSITY OF LONDON

The College prepares students by full-time and by part-time study for the Internal B.Sc. (Special) Degrees of the University of London in Chemistry, in Mathematics and in Physics and for the B.Sc.(Eng) degree in Metallurgy.

There are full-time courses for the External B.Sc. (Special) Degrees in Botany and in Zoology

Internal B Sc.(General) Degrees under revised regulations may also be taken by full-time, part-time or evening courses in the above science subjects together with Geology.

Preliminary requirements are met by similar courses of Intermediate standard in these subjects

Courses, both full-time and part-time, are available for examinations of the Royal Institute of Chemistry, the Institution of Metallurgists and the Institute of Physics.

Facilities are provided for full-time and part-time research and postgraduate work and short courses are held on a variety of special topics

Application forms for enrolment for the Academic year 1957-8, and the College prospectus may be obtained from the Secretary.

UNIVERSITY OF MANCHESTER

The next session commences on Thursday, October 3, 1957

NORTHERN POLYTECHNIC

HOLLOWAY ROAD, LONDON, N.7
Principal: A. S M Symons, Ph.D., B.Sc., A R C S., D.I.C., F.Inst.P.

Day and evening courses for the internal and external B.Sc. degree examinations of the University of London in chemistry, physics, mathematics, botany, zoology and geology. Full-time and Sandwich Courses for the Diploma in Technology in Applied Chemistry. Facilities for research in science (full-time and part-time) Courses for the M.Sc. degree by written examination and dissertation in mathematics, physics and chemistry. Day and evening courses for the Grad.R.I C. and Grad Inst.P. examinations. Courses are also conducted (day and evening) for the intermediate examination of the Pharmaceutical Society, intermediate B.Pharm. and first medical examinations of the University of London, and for the general certificate of education. Next session begins September 23, 1957.

Prospectus on application. Tel.: NORth 1686.

CHELSEA POLYTECHNIC

(College of Advanced Technology)
DEPARTMENT OF PHYSICS

Session 1957-58: Postgraduate Evening Courses begin September 23, 1957 Subjects available: Acoustics and Vibration Physics; Nuclear Physics; Optics; Physical Electronics; Quantum Mechanics; Semiconductors; Electro-magnetism. Ancillary Courses include Electronic Circuit Theory. Enrolment: Tuesday, September 17, and Wednesday, September 18, 6-8 p m.

Further details and application forms from the Secretary, Physics Dept., Chelsea Polytechnic, Manresa Road, S.W.3. FLAxman 5747.

NORTHAMPTON COLLEGE OF ADVANCED TECHNOLOGY

LONDON
ST. JOHN STREET, E.C 1
THE CHEMISTRY OF COLOUR PHOTOGRAPHY

A COURSE OF SIX LECTURES will be delivered in the Department of Applied Chemistry by C. Heitler, B Sc. on MONDAY EVENINGS at 6 30 p m., commencing SEPTEMBER 30, 1957. Fee for the course 10s. Further particulars from Secretary.

OFFICIAL APPOINTMENTS

D.S I.R REQUIRES TWO ASSISTANT EXperimental Officers at Building Research Station, Garston, Herts, to assist with field interviews and analyses of field data associated with studies of relationship of building design and equipment to user requirements. Qualifications: G.C.E. Advanced level in two science or mathematics subjects or equivalent. Pass degree or equivalent in psychology or social science an advantage. Salary £370 (age 18) to £800 (men). Women slightly less but equal pay scheme. Five-day week.—Forms from Ministry of Labour and National Service, Almack House, 26-28 King Street, London, S W.1. Quoting G279/7A. Closing date September 21, 1957.

UNIVERSITÉ DE MONTREAL

DÉPARTEMENT DE PHYSIQUE
MONTRÉAL, CANADA
ATTACHÉ DE RECHERCHES

The Attaché de recherches will be invited join the 500-kilovolt accelerator group, to partic pate in the present work on fast neutrons and, he so desires, to initiate other research wor Teaching duties can be arranged if desired, but speaking knowledge of French would then be r quired Candidates should preferably have Ph D degree in physics and have some experien in the field of nuclear physics, either theoretic or experimental The initial salary will be a proximately in the range of $5,000 to $6,000 p annum, plus an allowance towards travelling e penses. This post is available immediately.

Applications should include a curriculum vit and the names of two physicists as referee They should be addressed to the Directeur, D partement de Physique, Université de Montré Case Postale 6128, Montréal 2, Canada

---

UNIVERSITÉ DE MONTREAL

DÉPARTEMENT DE PHYSIQUE
MONTRÉAL, CANADA
THREE TEACHING POSTS AVAILABLE

Applications are invited for three teachin posts ranging up to that of Professeur titulai and involving both research and teaching. speaking knowledge of French is required. Th Département de Physique is presently active in th following fields: inelastic scattering of fa neutrons, nuclear emulsions, cosmic rays and electron diffraction in gases Both theoretical an experimental physicists interested either in thes or other fields are invited to apply. Researc facilities are good Salary and title will be commensurate with experience, and an allowance wi be made towards travelling expenses The University provides free life insurance and a retirement plan. These posts are available immediately.

Applications should include a curriculum vita and the names of two physicists as referees, an should specify the salary required They should b addressed to the Directeur, Département d Physique Université de Montréal, Case Postal 6128, Montréal 2, Canada.

UNIVERSITY OF OTAGO

(DUNEDIN, NEW ZEALAND)

Applications are invited for two posts as either Lecturer or Assistant Lecturer in Mathematics. Salary range is Lecturer £1,025 by £50 to £1,275 per annum; Assistant Lecturer, £780 by £50 to £880 per annum.

Further particulars are available from the Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C 1. Applications close in New Zealand and London on October 15, 1957.

LABORATORY TECHNOLOGIST (MALE) required by West African Institute for Oil Palm Research, Nigeria, for tour of 12 to 24 months in first instance, either (a) with prospect of pensionable employment or (b) on temporary terms. Salary scale (including inducement addition) (a) £774 rising to £1,284 a year, or (b) £834 rising to £1,386 a year with gratuity at rate £100/£150 a year. Commencing salary according to qualifications and experience. Outfit allowance £60 normally payable. Free passages for officer and wife. Assistance towards children's passages and grant up to £150 annually towards maintenance in U K. Liberal leave on full salary. Candidates must be A.I.M.L.T. or equivalent and have good knowledge of botany and chemistry with a sound grounding in physics and mathematics Training in analytical work or previous experience in the experimental field of biological research an advantage. Special consideration will be given to qualified West African applicants on appropriate terms.—Write to the Crown Agents, 4 Millbank, London, S W.1. State age, name in block letters, full qualifications and experience and quote M3/44270/NF.

SCIENTIST REQUIRED BY THE National Coal Board's Coal Research Establishment, Stoke Orchard, near Cheltenham, Glos., for interesting and varied work on fundamental studies of the problems of cleaning and dewatering fine coal which requires some knowledge of physics, physical chemistry and mechanics. An aptitude for research and an inventive mind are required, and a degree, or equivalent qualification, in a relevant subject is essential. Salary according to qualifications and experience between £630 to £1,360 male, £614 to £1,273 female Superannuation scheme, etc.—Write for application form to Personnel Officer (X/890C), at above address before September 18, 1957.

LONDON COUNTY COUNCIL PADDINGTON TECHNICAL COLLEGE

Saltram Crescent, W.9
Tel. Ladbroke 1343–4

DAY AND EVENING CLASSES

ENGINEERING AND SCIENCE CLASSES:

Mechanical, Electrical, Machine Shop, Motor Vehicle, and Post Office Engineering, Electrical Installation, Electrical Technicians' Work, Gas Fitting, Heating and Ventilating, Industrial Administration, Medical and Science Laboratory and Surgical Technicians' Work, Glasswork, Oxyacetylene Welding, Chiropody, General Certificate of Education (Advanced Level).

WOMEN'S CLASSES:

Cookery and Catering, Dressmaking, Millinery, Flower-making, Ladies' Tailoring, Nursery Training, Soft Furnishing, Loose Cover Cutting.

Prospectus on application to the Principal:
A. T. Linley, B.Sc., F.R.S.A., A.M.I.Mar.E., M.I.Prod E.

ENROLMENT:

Day Classes	8–13 September	9.30–12.0
Evening Classes	16–20 September	6.0 – 8.0

BRITISH PUBLIC SCHOOLS AND THE FUTURE

DISCUSSION about the future of the British public schools cannot be confined to educational principles alone. This has been well brought out in recent months when new books, broadcasts and public lectures have shown that some of those who wish to see the public schools survive are as capable of radiating as much heat without light as those whose professed aim is to abolish the public schools as quickly as possible. This is not difficult to understand. The public school is a peculiarly British institution that is the envy of other countries which do not understand it and the despair of many British people who maintain that, as at present constituted, public schools have no place in a democracy but recognize that they have made an immeasurable contribution to the British way of life by the quality of education they provide.

As Vivian Ogilvie has shown, the story of the public schools is a baffling one[1]. The term 'public school' came into use about the beginning of the eighteenth century and was reserved for some of the best-known grammar schools like Eton, Winchester, Canterbury, Rugby and Harrow. A hundred years ago the Public Schools Commission recognized only nine schools. To the Fleming Committee a 'public school' denoted any school in membership of the Governing Bodies' Association or of the Headmasters' Conference; there are now nearly two hundred such schools[2]. Of these, about half are independent and the others are aided either by grants from the Ministry of Education or by local education authorities. Thus about a half the public schools secure aid from public funds and about a half are predominantly day schools.

To the majority of people, however, the public schools are the independent boarding schools and it is these schools which cause greatest controversy. 'Abolitionists' believe that if the independent boarding schools could be satisfactorily integrated into the national educational system, the direct-grant, aided and maintained schools would present no great problems; nor would the independent day schools. The knowledgeable abolitionist, however, is well aware that the best English public schools are among the finest of educational institutions, and to destroy them would be a piece of incalculable educational folly to the country and the world.

The reasons why parents sent their sons to public schools at the beginning of the nineteenth century are not very different from the reasons why parents send their sons to-day. These were clearly defined by the headmaster of Eton College, Mr. Robert Birley, in a public lecture organized as one of a series by the Director of the Institute of Education, University of Sheffield[3].

Parents send their sons to public schools mainly for three reasons. They are genuinely prepared to make considerable financial sacrifices so that their sons may attend a good school to receive a well-balanced education. Since they are prepared to make these sacrifices, they prefer their sons to attend boarding schools which will best prepare their sons for life in society. Even the opponents of public schools are prepared to concede that these are genuine educational reasons which merit respect and support. The third reason cannot be regarded as strictly educational and is the one which public school supporters find it more difficult to justify; many parents strongly defend the public schools not only on grounds of sentiment, but also because they are well aware that membership of them conveys social advantages which will help their sons in later life.

That many public schools provide a good education few would deny; they have done much to set and raise educational standards. Despite much nonsense talked about religion in the public schools, for example, the school chapel has done much for the development of character in many boys. In secular education, public schools have benefited by attracting staffs of quality; in the nineteenth century the assistant master at a public school was a person of considerable status in society, was adequately paid and, academically, often of the stature of a Fellow of a College. To-day, public schools still attract better masters than the grammar schools; higher salaries and smaller classes are great incentives. Often the standards set by the public schools have served to raise the standards of grammar and other secondary schools; this influence still exists. Decline of the public schools would almost certainly lead to a decline in standards at schools in the national educational system.

The existence of public schools can be justified by the contribution its scholars make to life and society. Whether leadership owes its origins mostly to genetics or the dicta of well-known military commanders is debatable; that most public school boys have poise and self-confidence is well known. Living together in school enables many public schoolboys to move with grace and distinction in many walks of life. This is a quality which is not so abundant among our young men that we can afford to obliterate it by doing away with our boarding schools without adequate reasons for so doing.

The third demand which parents make on the public schools is impossible to justify on educational grounds and has social, political and moral implications. Many parents—and they may be more than the headmaster of Eton would have us believe—send their sons to public schools because membership of these schools will be of service to them in their future careers. Although this charge may be exaggerated—the full effects of the establishment of grammar schools under the Education Act of 1902 have not yet been seen—the public school system undoubtedly confers advantages on its products which are denied to those from State schools. A system which enables less able men to come to the top and prevents the abler from so doing cannot be justified on human, economic or moral grounds.

But even this does not provide a case for abolishing schools which have so much to commend them educationally; if the wrong boys are getting into public schools, other means of selecting them must be found. At present the main criterion for getting into a public school is the ability of parents to pay the fees demanded. Despite improved standards of the Common Entrance examinations, few cases are known of boys failing to get into public schools of the parents' choice provided the parents can pay their fees and have certain associations with the schools. There are some, like the High Master of St. Paul's School, who is prepared to defend the parent's right to spend his money in buying a public school education for his son[4]. Thoughtful supporters of the public schools recognize that few parents can afford that privilege and have queasy consciences about a system which confers marked educational and social advantages on boys who may have little merit in them.

The difficulty, of course, is to find a system of selection which would throw the public schools open to all. Many in the public schools are anxious to enlarge their areas of recruitment because they are convinced that their schools have something of value to offer to individual boys and to the educational system as a whole. These headmasters, and others, showed their readiness to accept the main proposals of the Fleming Report; these proposals need to be re-examined. Under both the two main proposals put forward by the Fleming Committee, the general effect would be to reserve some places in public schools for scholars whose parents would be unable to pay the high fees demanded. By a Government decision in 1946, the responsibility for paying fees for selected scholars would devolve upon the local education authorities. There is little doubt that this Government decision was hopelessly impractical and, during the deliberations of the Fleming Committee, was opposed by every representative of local education authorities. It is not surprising, therefore, that with few exceptions, local education authorities have done nothing to carry out the Fleming proposals. To spend £400 per annum on sending a boy to a public school with which the local authority has no affiliations is asking a great deal of that authority; one-tenth of that sum is sufficient to send the boy to the local grammar school of which the authority is so rightly proud. Experience since 1946 has shown that, if boys whose parents have limited means are to be admitted to public schools, their fees will have to be paid directly by the Treasury.

To dismiss this proposal as beyond the country's financial resources invites comparison with the introduction of compulsory education for all in 1870 or the establishment of new universities over the past seventy years. To the argument that the State would not be justified in spending so much on individual boys comes the answer that the number of boys being given 'free' places at universities is still increasing. To begin with, a small number of places at public schools could be reserved for 'free-place' scholars whose fees would be paid direct by the Treasury; the numbers could be steadily increased until the number of 'free-place' scholars exceeded the number of fee-paying scholars. Such a proposal will undoubtedly be greeted with horror by those who wish to see the public schools carry on as they have always done. The more long-sighted supporters of the public schools will see that, owing to certain trends in contemporary society, proposals of this kind represent the public schools' main hope of survival. It should be borne in mind that fee-paying scholars are likely to get even more from their boarding school education if a considerable number of their colleagues come from walks of life very different from their own.

Means of administering such a scheme could, in principle, follow the proposals set out in the Fleming Report, which recommended the appointment of a central advisory committee responsible to the Minister of Education and the members of which would include representatives of local education authorities, governing bodies of public schools and the teaching professions, with other persons not connected with the conduct or administration of education.

There remains the cardinal problem of selection. If financial aid were made available by the Treasury, what method of selection should be adopted to bring the most suitable boys to the public schools? More difficult still, what kind of boys would be selected? To which schools should boys be sent? No easy solutions to these questions are likely to be found, as was indicated in a recent broadcast discussion between C. A. R. Crosland and Sir John Wolfenden[5]. To fail to make the attempt, however, would be unjust both to those individuals likely to profit by a public school education, to the schools themselves and to the national education system.

The selection of schools to which boys would be sent should present no great difficulty. Schools should be allowed to participate only if they wished to do so and if their academic standing and reputation were such that the expenditure of public moneys on 'free-place' scholars could be justified; according to Ogilvie there are between sixty and seventy such schools. Common Entrance examinations standards for *all* boys wishing to enter these schools might have to be raised. Those schools of lesser quality which cater mainly for boys of limited intellectual ability but whose parents have ample means or are prepared to make sacrifices in order to buy their sons a place in society should not be allowed to participate in any new arrangements. The increasing number of grammar school boys who proceed to the universities is likely to cause the lesser public schools to wither away with no great loss to the boys who attend them, or to the nation.

What qualities would be looked for in boys selected to attend outstanding public schools as non-fee-paying scholars? The simplest criterion would be that of intellect; this would be the most easy to discern. To produce a form of Platonic institution, however, where all the best brains were gathered together, would be undesirable both for the boys and for the national educational system as a whole. Much more desirable would be the selection of those qualities of character similar to those looked for in Rhodes Scholars who proceed to Oxford from Commonwealth countries and the United States. These Scholars have good intellects but are not necessarily outstanding on this count alone; much more attention is given to their ability to mix with their fellowmen and their desire and aptitude to serve them. The criticism could fairly be made that by this method an élite community would still be created at the public schools. These boys would differ in one important respect from the élite which attend the public schools to-day; they would be deliberately chosen and not owe their positions in school to their parents' wealth.

Critics would say that it is impossible to discover these qualities in boys of thirteen. The same critics were uncompromising in their opposition to the use of group selection methods for discovering potential officers in the Army during the early years of the Second World War. The contributions of Colonel J. R. Pinsent and his War Office Selection Boards in making the best use of man-power is now accepted as one of the most important educational and social discoveries of the War. The other Services were not slow in following Pinsent's lead, while a recent report of the Civil Service Commissioners has shown how group selection methods can be used in the selection of candidates for important positions in the Civil Service[6]. These methods are being increasingly used in industry for the selection of potential executives. Similar methods could be devised to select suitable candidates for public school places.

Experience already gained at Service institutions with public-school status like Dartmouth, Sandhurst, Welbeck and Cranwell would be of use in helping to formulate the selection methods. The use of group selection procedures would be an extension of the proposal put forward by the Fleming Committee for the setting up of regional interviewing boards.

Besides non-fee-paying scholars recruited in this way, room might have to be found for other groups of boys. There are those from geographical areas where opportunities for receiving education worthy of their intellectual level are few or non-existent; these boys from rural areas deserve the most sympathetic consideration. A case could be made out for boys from broken homes, but it is difficult to justify the high expenditure involved; it might also, as Sir John Wolfenden has suggested, lead to more frying pans being thrown on Friday nights. A better case could be made out for able boys who come from homes where the parents are hostile to the further education of sons who will soon be bread-winners, or because of peculiar difficulty caused by the nature of the father's occupation.

Schemes for sending poor boys to public schools are, of course, fraught with other difficulties. There is the danger that chosen boys will not fit into the social life of the school, or will become misfits in their families. This is a danger which besets any boy who moves into a different educational level from that of his parents; it is doubly dangerous when he moves into an obviously different social stratum. Experience already gathered at several public schools which have taken non-fee-paying scholars—Mill Hill has taken considerable numbers—shows that, with wise guidance from headmasters and housemasters, this danger can be overcome.

There is also the danger to the grammar schools. A policy of systematically 'creaming off' able boys to be sent to public schools could deprive the grammar schools of promising material and lead to the debasing of their own standards. This danger may be more apparent than real. In Britain as a whole there are still insufficient grammar school places for all boys who could profit by them; the number of boys who could be accommodated in the sixty or seventy public schools would represent a small fraction of the total available in the country at any one time.

What is now needed is a new look at the place of the public schools in the general educational system and the life of the nation. The Minister of Education should invite his central advisory councils for education to re-investigate the proposals contained in the Fleming Report or appoint a working party to see how far these and other proposals it recommends are practicable in the next few years. These deliberations should be carried out in a national atmosphere free from the polemics of those who cry "hands off the public schools!" or from partisan statements contained in documents like the Labour Party's "Challenge to Britain". Those responsible for administering the more important public schools are aware that there is a growing and irresistible trend towards greater equality in society. They realize that, unless they can find a means of opening their doors to a greater range of scholars from all social classes, they may find them shut by political action. They recognize that a society divided by educational institutions, the main criterion of which for entry is money, is unlikely to be acceptable much longer in Great Britain.

As the leaders of the main political parties are themselves products of the more important public schools, it is to be hoped that they can persuade their followers to discuss the future of the public schools in a spirit of goodwill where the only consideration is how they can best serve the interests of the individuals and the nation. Despite their anomalous position in the British educational system, to lose them would be a national disaster. As Sir John Wolfenden has well written[7], public schools "embody an immense heritage of accumulated experience. They have in the past shown themselves capable of evolutionary change. There is every reason to expect that, again in the twentieth century, they will be capable of meeting the new requirements of a new social and economic situation and of making a yet wider and deeper contribution to the national life than they have done in the past".

No mention has been made of public schools for girls or of independent preparatory schools. They would have to be considered in the light of developments inside public schools for boys.

INSTINCTIVE BEHAVIOUR IN ANIMALS AND MEN

l'Instinct dans le Comportement des Animaux et de l'Homme

Par M. Autuori, M.-P. Bénassy, J. Benoit, R. Courrier, Ed.-Ph. Deleurance, M. Fontane, K. von Frisch, R. Gesell, P.-P. Grassé, J. B. S. Haldane, Mrs. Haldane-Spurway, H. Hediger, M. Klein, O. Koehler, D. Lehrman, K. Lorenz, D. Morris, H. Piéron, C.-P. Richter, R. Ruyer, T.-C. Schneirla, et G. Viaud. Pp. iv+796. (Paris: Masson et Cie, 1956.) Broché, 6,500 francs; Cartonné toile, 7,200 francs.

THIS book consists of the papers, complete with illustrations and subsequent discussions, delivered at a symposium entitled "Instinct in the Behaviour of Animals and Man", which was arranged by the Singer–Polignac Foundation in June 1954. The papers and discussions are in the language of their contributors, French, German and English. The interest of this symposium is two-fold: first, the very wide range of organisms covered, and the inclusion of papers on instinctive behaviour in man, a very neglected aspect of this field; secondly, the fact that it afforded an opportunity for a further round in the important controversy between the so-called 'objectivist' school of ethologists led by Drs. K. Lorenz and N. Tinbergen, and their opponents from the ranks of the psychologists, led by Drs. T.-C. Schneirla and D. Lehrman.

It has always appeared unfortunate to some students of behaviour that the vast majority of the experimental evidence on which Lorenz's theory of instinctive behaviour is based has been derived from experiments on vertebrates. In the present symposium a number of papers on insects were given, including a notable summary by Prof. K. von Frisch of the behaviour of honey bees, and it is interesting to notice the emergence in the discussions of an idea that both innate and acquired behaviour in insects differs qualitatively from that of vertebrates by reason of the fundamentally different arrangement and operation of association centres in the central nervous system. Of great interest but of dubious value are the papers dealing with innate behaviour in men. This has always been a blind spot in the theorizing of human psychologists, and most followers of Freud and other classical analysts are aware of this deficiency; in fact, despite the investigations of infant psychology by Melanie Klein and her school there is little evidence for instinctive behaviour in humans. Thus the paper of Dr. M.-P. Bénassy in the present volume, attempting to recast the psychoanalytical theory of instinct, is of great interest, even if somewhat premature in face of the meagre data available.

It is, however, in the factual and theoretical papers on instinct in fish, birds and lower mammals that the back-bone and centre of interest of this symposium is to be found, and it is a pleasure to note how most speakers applied themselves closely to their required subject. Dr. Lorenz, indeed, applied himself so closely as to give what is probably one of the most precise and telling definitions of instinctive motor patterns ever made, to the exclusion of that part of his theory which deals with the role of the nervous system in instinctive behaviour, the kernel of which is his concept of the innate releasing mechanism. To some workers, especially physiologists, this may seem a cleverly calculated lapse, since it is precisely in this aspect of particulate function in the nervous system that his theory seems most fallible. In pursuit of the central controversy, the papers of Drs. Lehrman and Schneirla express their critical attitude towards the objectivist school; the title of Dr. Schneirla's paper, "Interrelationship of the 'Innate' and the 'Acquired' in Instinctive Behaviour", does perhaps express the core of their attitude, that Lorenz and his co-workers under-estimate the part that learning can play in the appearance of apparently innate behaviour patterns.

It would be foolish to expect that one symposium would result in the solution of this controversy about instinct; yet there are signs here and there in the discussions of a more liberal attitude by both sides in the argument, and surely this must be regarded as a most satisfactory outcome by the organizers. This stimulating set of papers is unfortunately marred by bad proof reading, and in a number of cases by such poor transcription or translation as to make certain passages meaningless. This is particularly so in regard to papers and discussions in English, but it also occurs in certain German papers. In places, the discussion reads as though certain questions and answers had been omitted. Page numbers are occasionally transposed in the text and in the table of contents several incorrect page numbers are given. These minor criticisms apart, however, the book may be recommended as a great fund of information and informative speculation on all aspects of 'instinct'—however one cares to define it.

P. T. Haskell

TOWARDS A STANDARD TERMINOLOGY IN STATISTICS

A Dictionary of Statistical Terms

By Prof. Maurice G. Kendall and Dr. William R. Buckland. Pp. x+493. (Edinburgh and London: Oliver and Boyd, Ltd., 1957. Published for The International Statistical Institute.) 25s. net.

FOWLER'S "Modern English Usage" describes a dictionary as "concerned merely with words regarded as materials for speech", but adds, "since some information about the thing is necessary to enable the words to be used rightly, and opinions differ on the how much of this, most dictionaries contain some matter that is strictly of the cyclopædic kind". This book is a dictionary in the true sense, although much material of the encyclopædic type is included. It is the first comprehensive work of reference of its kind and is needed. Scientists who use statistical analysis occasionally and professional statisticians should find it of most value—in the latter case mainly for terms outside their own special interests. It is not a book for the student.

The contents form a dictionary of terms with definitions in English, and four glossaries of the equivalent names in French, German, Italian and Spanish, in alphabetical order of the particular language. The glossaries give page references to the English definitions. The text is clearly printed and presented, in single column, and there seem to be few misprints of any importance. The terms included are mainly those which occur, in English usage, primarily in the science of statistics, but there are also a number from mathematics and other sciences, which are statistical in nature or important in the development of the subject. There are also definitions of terms current in Italian, for which there are no English equivalents. The many cross-references are an aid in tracing meanings.

It would be easy to criticize this book for its limitations—omissions of terms, slightness of historical references, arbitrary statements on controversial points—but Prof. M. G. Kendall has ably forestalled these criticisms in a paper read at the 1953 session of the International Statistical Institute. Most of the limitations are due to the rapid growth of the science and the lack of a tradition of standard terminology. The authors have aimed at producing a useful, medium-sized dictionary within a reasonable time, and, at present, no more could fairly be asked. It must be considered by these aims and, in particular, by the quality of the definitions.

These are, on the whole, accurate and clear so far as is possible. Thus the confusions in the definitions of, say, truncated and censored distributions are due to usage and not the authors. The standard, for terms on the borderline of statistical science, is not always so high; some demographic definitions, for example, standardization, life tables, are imprecise and even, perhaps, misleading. In a few instances descriptions of procedures are too condensed to be followed in practice, for example, Yates's correction.

It is arguable that the value of this work would be even greater if the material of an encyclopædic nature, particularly in the definitions of the more familiar terms, was reduced to allow for a wider scope and more references—in fact, if it was even more of a 'dictionary'. Perhaps it will tend this way in future editions.

W. Brass

INTRODUCTION TO MICROBIOLOGY

The Microbial World

By Prof. Roger Y. Stanier, Prof. Michael Doudoroff and Prof. Edward A. Adelberg. Pp. xxii+682. (Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1957.) 8 dollars.

THE modern microbiologist, if he is to appreciate his subject to the full and if he is to make significant contributions in his own discipline, must, as the authors of this book insist, have a sound grounding in general biology with emphasis on the structure and mechanism of the cell. But that is not all; he must also have a sound knowledge of organic chemistry and biochemistry.

This book is directed to the beginner in microbiology, but without adequate chemical training he is unlikely to appreciate fully the sketches on the biochemistry and nutrition of micro-organisms. This being accepted, it must be said at once that the book is admirable for its purpose. It is obviously impossible, even were it desirable in a book for beginners, to treat in detail any one facet of microbiology as we now know it, but enough is said on each topic to arouse the interest of the reader.

The authors have had the happy idea of giving at the beginning of the book a selected bibliography of treatises on the history of microbiology, on the general properties of bacteria and viruses, on micro-organisms in disease, and on their industrial applications. They then proceed to construct a broad chart of their territory. There is little or nothing of importance in microbiology, particularly, as one might expect, in bacteriology, which is not dealt with. The text is well supported by many excellent illustrations, both line and plate. A good example is that which explains diagrammatically the reason for the inhibition of precipitation when either antigen or antibody is present in excess.

The authors have emphasized their own insistence on the value to the microbiologist of a biological background by including as Part 3 chapters on genetics, evolution, variation and natural selection of living organisms, supported by some physiology, biochemistry and nutrition. The events within the living cell are basically similar, and it is well that the importance of their study in micro-organisms should be recognized from the outset. This is an easy book to read and can be recommended to the beginner, and to those of greater stature who are willing to be entertained and even, perhaps, instructed.

By J. Wartnaby. (Ministry of Education: Science Museum.) Pp. v + 18 + 8 plates. (London: H.M. Stationery Office, 1957.) 2*s*. net.

THE International Geophysical Year began on July 1, and these three pamphlets for the general reader were published in June. "The Guide to the I.G.Y." is produced by the British National Committee for the International Geophysical Year, and contains contributions by members on their respective subjects—solar activity, cosmic rays, the ionosphere, aurora and airglow, geomagnetism, meteorology, glaciology, longitudes and latitudes, oceanography, and seismology, preceded by a foreword by the chairman, Sir James Wordie, and a summary by the secretary, Dr. D. C. Martin, of the interrelation of the subjects. An account of the United States satellite plan has been provided by the U.S. National Committee. The inside front cover carries a map of the Antarctic with the positions of the various national stations and the inside rear cover the Geophysical Year calendar, with the dates of those special days and periods it has been possible to fix in advance for more concentrated observations. There will be other special periods, the Special World Intervals, on occasions of unusual solar phenomena, such as solar flares. The pamphlet concludes with a description of relatively simple apparatus for observing sunspots and roughly recording changes in magnetic variation which could be assembled in a school physics laboratory. The newer and less-tried methods of carrying instruments by rocket and artificial satellite are perhaps given undue prominence, and there is no mention in the text of the World Meteorological Intervals shown in the calendar. The pamphlet should be useful to a science teacher for preparing lessons on the Geophysical Year.

The Unesco pamphlet gives much more, but not altogether overlapping, information for sixpence more than the Guide. It includes many quantitative geophysical data and a detailed account of the history of the plan for the Year, naturally stressing the financial support given by Unesco. It goes into greater detail than the Guide, stating fully, for example, as the Guide does not, the reasons for the selection of particular dates and periods for the specially concentrated observations, and under "Measuring the Earth" it explains that it is hoped to increase the accuracy of knowledge of the distance between the continents from roughly 100 m. to 30 m. The pamphlet concludes with a useful glossary. It is not necessary to go to Antarctica to study lee-wave clouds as might be thought from the caption to a photograph of one, and there is no detailed calendar. Neither the Guide nor the Unesco pamphlet says enough about what will be done in the special days and periods; it is merely stated that observations too complex to be made daily will be made during them. Altogether, however, the Unesco pamphlet is strongly to be recommended.

The Science Museum pamphlet provides an easily readable, broadly popular, mainly qualitative, account of the aims and methods of the Geophysical Year.

PRIMES AND FACTORS

Factor Table for the First Ten Millions

Containing the Smallest Factor of Every Number not Divisible by 2, 3, 5, or 7 between the Limits 0 and 10,017,000. By Derrick Norman Lehmer. Pp. xvi+476. (New York and London: Hafner Publishing Company, 1956.) 160*s*.

List of Prime Numbers from 1 to 10,006,721

By Derrick Norman Lehmer. Pp. xv+133. (New York and London: Hafner Publishing Company, 1956.) 107*s*. 6*d*.

PRIME numbers have interested professional and amateur mathematicians for many centuries, and continue to do so. Many have made factor tables and lists of primes, culminating in the great factor table of Kulik to 100 millions; this remains in manuscript and is inaccessible, difficult to read, and full of errors.

For practical purposes the two volumes produced by D. N. Lehmer form the definitive tables for those needing factors of numbers and using primes not exceeding ten millions. These two volumes first appeared in 1909 and 1914. The first gives the least factors of all numbers up to 10,017,000 that are not divisible by 2, 3, 5 or 7, in an easily usable though (because of the absence of multiples of 7) not absolutely direct form. The second volume lists all primes from 1 to 10,006,721 in a manner allowing the rank (that is, *n* for the *n*th prime) to be easily extracted.

Lehmer's tables superseded the considerable earlier efforts of Burckhardt (first three millions), James Glaisher (fourth, fifth and sixth millions), Dase (seventh and eighth millions) and Dase and Rosenberg (ninth million). Of these, Glaisher's were remarkable for accuracy when they appeared, but all are surpassed in this respect by Lehmer's table. In the list of primes the only known errors are:

Page	Column	Line	For	Read
11	13	1	8151	8051
14	30	55	51	47
99	20	heading	224	724

although there are several missing rules, and a few misprints in the Introduction. No error is known in the Factor Table.

Lehmer's tables have been out of print for some time, so that the demand, constant over decades though not great, has led to a high scarcity price for second-hand copies, which are all too rare. It is therefore with much pleasure and interest that this new edition is received, of a standard, definitive and highly accurate work; it is time for the volumes to be generally available again.

The reproduction of the original tables was good, but the figures, typed and reduced, are considerably too small and the large page awkward to use; legibility was reduced by use of a yellowish paper. It is thus pleasant to record the use of a whiter paper, even though the page has, inevitably, the same layout and is of the same unwieldy size. One criticism may be mentioned; it is a pity that known errors were not corrected—as might easily have been done—before reproduction. Instead, an arbitrary hand-marked copy has been used, with errors apparently all noted, but no corrections given. The interest of a user of the original copy in early prime fours is unexpectedly evident! This is, however, only a minor criticism of a useful job well done.

We may, perhaps, note some further tables. There is the table published in 1951 which was prepared by Kulik, Poletti and Porter giving primes in the 11th million, and the manuscript factor table for this million prepared by N. G. W. H. Beeger in Amsterdam. There are also two sieves of primes, computed electronically on cards—one by D. H. Lehmer (son of D. N. Lehmer) prepared on SWAC at Los Angeles to about 35 million, and one prepared by D. C. Clayden on the pilot ACE at the National Physical Laboratory. The latter has been used to check a list of primes, prepared on EDSAC at Cambridge by the writer, that extends at present to 17 million. Thus Kulik's great work stands alone, even in the present day of electronic computation, just as Lehmer's tables are the outstanding published source.

J. C. P. Miller

OCCURRENCE OF STONE ARTEFACTS WITH *AUSTRALOPITHECUS* AT STERKFONTEIN

Part I

By Dr. J. T. ROBINSON
Transvaal Museum, Pretoria

IN May 1956 Dr. C. K. Brain, at that time working in the Department of Vertebrate Palæontology and Physical Anthropology of the Transvaal Museum on the australopithecine-bearing breccias, discovered some stone artefacts in breccia rubble near a small pit 55 ft. west of the Sterkfontein Type Site. The latter site yielded the *Australopithecus* and associated faunal material from Sterkfontein. At this time I was in the United States, and at my request a narrow zone of overburden was removed between the West Pit and the Type Site, revealing a continuous deposit of breccia between the two. Artefacts were found in the overburden, hence further removal was halted. After my return, the director of the Archæological Survey, Mr. B. D. Malan, agreed to collaborate with this Museum in certain aspects of the study of this site. To this end, Mr. R. Mason, assisted by Dr. Brain, conducted a pilot excavation of the overburden in January of this year (see Part 2). From mid-February until early June, I carried out an excavation of the *in situ* breccia in the region of the West Pit. This was made possible by a grant generously made available by Sir Wilfrid Le Gros Clark from the Boise Fund of the University of Oxford. Excavation has been discontinued, owing primarily to lack of funds, but a great deal remains to be done. The results already obtained are of obvious importance and are thus being published now; but it is manifest that more evidence is urgently needed before detailed conclusions can be drawn.

The newly exposed breccia is referred to as the Extension Site to distinguish it from the Type Site. A permanent grid base (steel wire on concreted steel rods) was set up at datum-level using a surveyor's level—which was also used for making a detailed map. 2-ft. grid intervals were used and 1-ft. levels were adhered to as nearly as the material allowed. Breccia was removed by means of a two-stroke drill and steel wedges. All the breccia removed was *in situ*, being part of a very large solid mass. Only material found *in situ* in this mass has been used; the original finds in rubble have thus been left out of account.

Stratigraphy. The Extension and Type Site breccias were regarded as being identical when the first artefacts were found, hence the latter were thought to be coeval with the Type Site *Australopithecus*. By the time the site had been fully prepared for excavation this conclusion seemed to me improbable, and excavation soon revealed that at least three breccias are involved. In the West Pit area a superficial, chocolate-brown breccia, with a maximum thickness of about 2 ft., overlies a much thicker red-brown breccia. The two are separated in this region by a rather thin stalagmite of variable thickness. The brown breccia contains fairly abundant remains of *Equus* but, so far, neither artefacts nor australopithecines. A volume of roughly 250 cu. ft. of red-brown breccia has yielded fifty-eight artefacts, abundant micro-mammalian remains, some artiodactyl and carnivore, but no *Equus* material, as well as M^1, dm^2 and dm^1 of *Australopithecus*. The latter tooth is fragmented but the others are well preserved, especially M^1, which appears to fall easily within the observed range of variation of the Type Site sample, and its identification is in no way uncertain.

The red-brown breccia affords clear evidence of a still older breccia in the neighbourhood in the form of inclusions, ranging in size from small pebbles to blocks 1 ft. across. These consist of consolidated breccia of a paler colour than the main mass and have sharply defined edges. They must consequently have been incorporated in the accumulating red-brown breccia as fragments of an older and already consolidated breccia. The colour of these fragments is very similar to that of most of the Type Site breccia. Evidence is available which suggests that the Type Site breccia is older than the red-brown breccia and hence may be the source of these inclusions.

The Type Site breccia yielded much *Australopithecus* but no *Equus* material, and in this resembles the red-brown breccia. However, no artefacts were recovered from the large volume of breccia removed from the Type Site, and a recent detailed examination of the whole of this site and the rubble from it, as well as an appreciable volume of breccia in our storeroom, failed to provide any evidence of quartz, quartzite or diabase inclusions. In this it differs strikingly from the red-brown breccia. The west wall of the Type Site has an ill-defined unconformity which separates an upper level of breccia, which contains artefacts, from the typical Type Site breccia. The evidence thus suggests rather clearly that three breccias are present in the following order of decreasing age: pink, red-brown and brown. The pink breccia is known to be older than Swartkrans on climatic and faunal grounds. The lack of *Equus* in the red-brown breccia suggests that it also is older than Swartkrans although younger than the pink breccia; hence the age difference between these two is unlikely to be great since available evidence suggests that the age difference between the pink breccia and Swartkrans is not great[1]. No evidence is yet available regarding the relative ages of the brown breccia and Swartkrans.

The artefacts. Some of the artefacts from the red-brown breccia are unquestionably worked, while all but one are composed of material foreign to the site and its immediate environs. This indicates that a true lithic culture is being dealt with. Being in an undisturbed, consolidated breccia, the artefacts are rather clearly of the same age as the breccia. Any possible doubts on this score are dispelled by the fact that not only the consolidated brown breccia overlies the red-brown, but also the sterile layer of overburden which Mr. Mason has demonstrated to underlie the Middle Stone Age layer. This excavation has thus demonstrated conclusively, for the first time, the synchronous presence in one site of an australopithecine and a lithic culture. This industry is not of the most primitive order, and Mr. Mason has concluded (see below) that the most advanced artefacts indicate a late Oldowan or very early Chelles–Acheul stage in the African Stone Age sequence.

The presence of stalagmite overlying at least a part of the red-brown breccia indicates that a substantial dolomite roof must still have been present over this area after the accumulation of that breccia. This shows, contrary to the belief of some students, that very early Stone Age artefact manufacturers sometimes did live in, or in the immediate vicinity of, caves.

Who made these artefacts? Since no other hominids are known from Sterkfontein, it would seem that it must have been *Australopithecus*. However, the degree of advancement of the industry makes such a conclusion dubious. Furthermore, artefacts are apparently absent in the type site whereas *Australopithecus* remains are common. It seems improbable that this is due to the fact that this creature learned to make tools subsequent to the time of the pink breccia, but had already achieved a considerable degree of advancement by the time of the red-brown breccia. Perhaps the very fact that *Australopithecus* is common at Sterkfontein is an argument against it being a tool-maker, since in all other very early Stone Age sites remains of the tool manufacturer are extremely rare.

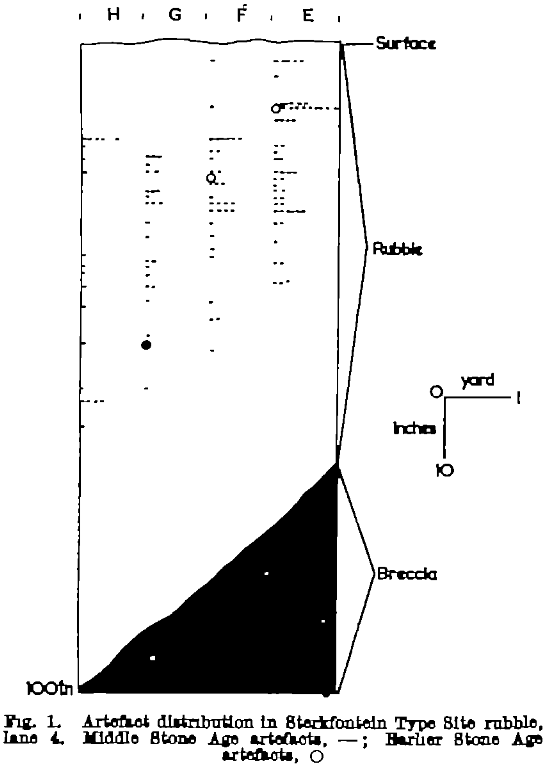

Fig. 1. Artefact distribution in Sterkfontein Type Site rubble, lane 4. Middle Stone Age artefacts, —; Earlier Stone Age artefacts, ○

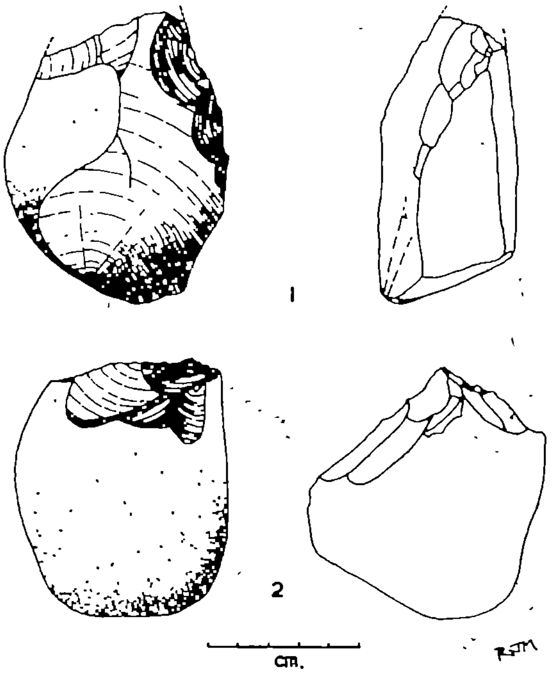

Fig. 2

The simplest explanation of the present facts seems to be that an early euhominid invaded the Sterkfontein area after the time of the pink breccia, but before the time of at least those levels of the red-brown which have been excavated.

It has been suggested above that the difference in time between the tool-bearing breccia of the Extension Site and Swartkrans, less than a mile away, is not great. In the lower levels of the latter site a few remains of *Telanthropus* were found. On anatomical grounds I have previously regarded this form as an australopithecine which had reached euhominid status[3]. If this view is correct, it is probable that this form had some sort of lithic culture. It is therefore not unreasonable to suppose that *Telanthropus* was the invading form responsible for the Extension Site artefacts. If it is assumed that the invader was not *Telanthropus*, then it must be concluded that *Paranthropus* and *Telanthropus* afterwards invaded the area and displaced or replaced *Australopithecus* at least, and perhaps the Extension Site tool-maker also. If *Telanthropus* displaced the latter form, it would imply that the former was the more advanced of the two hominids—in which case it is unnecessary to postulate the presence of the hypothetical form. If *Telanthropus* did not displace the other, it would follow that *Paranthropus*, *Telanthropus* and the hypothetical form simultaneously occupied the valley. Good evidence would be necessary before accepting such a complication. The most reasonable hypothesis at present is to attribute the red-brown breccia industry to *Telanthropus*, since this form is already known to exist in the area at about the right time-level. More evidence—which may well be present in the Extension Site—is urgently needed to shed further light on this interesting problem.

Part 2

By R. J. MASON

Archaeological Survey of the Union of South Africa

Excavation of superficial rubble. During 1956 Dr. C. K. Brain discovered stone artefacts in the upper level of the Sterkfontein breccia and in a superficial rubble of soil, dolomite and chert fragments overlying it. Early in 1957, with the assistance of Dr. Brain, I excavated part of the superficial rubble with the object of determining its relation to the underlying breccia. A base-line was laid on the north side of the site and 12 sq. yd. of the rubble excavated to reach the breccia between 46 in. and 100 in. below the surface. The deposit was excavated in 2-in. layers to enable the exact position of each artefact to be recorded. Numerous artefacts, but not fauna, were found in the rubble as follows: (1) three Later Stone Age artefacts, small microlithic scrapers, on and just below the surface; (2) 304 Middle Stone Age artefacts, from 3 in. to between 37 in. and 60 in. below the surface; these are mainly highly characteristic flakes of Middle Stone Age type, a few carefully prepared cores and dimple-scarred upper grindstones; (3) three possibly Earlier Stone Age flakes; (4) seven river pebbles in quartzite and diabase.

The eroded surface of the breccia supporting the rubble slopes evenly from 70 in. to 100 in. below the surface, except for a mount on the upper edge of the slope. The 317 artefacts found in the rubble are distributed in depth as follows: 85 per cent occur between 3 in. and 37 in.; 14 per cent occur between 37 in. and 60 in.; 1 per cent occurs between 60 in. and 65 in.

The stratigraphy is shown in Fig. 1. It is important to note that the lower 28–40 in. of the rubble is sterile except for one artefact, a position that eliminates the possibility of artefacts from the overlying, later rubble entering the underlying, earlier breccia. It seems highly probable that artefacts found in the breccia must be truly *in situ*, and of the same age as the breccia.

The rubble bed represents a sediment lying unconformably on the surface of the breccia. The Middle Stone Age artefacts are fresh in contrast to the worn, oxidized appearance of the three Earlier Stone Age flakes. The latter would appear to be derived from an earlier deposit. The rubble is therefore mainly of Late Middle Stone Age date, and may be placed at the end of the Transvaal Pleistocene, as typologically similar artefacts have been discovered in a well-represented end-Pleistocene faunal bed at Kalkbank, near Pietersburg. The rubble bed closes the Sterkfontein type-site sequence and extends its length to the end of the Stone Age. Despite unconformities, the site therefore provides a truly remarkable record of protohuman and early human life and activity.

The industry from the red-brown breccia. Dr. Robinson's excavation of the red-brown breccia produced not only australopithecine and other faunal evidence but also fifty-eight artefacts, the preliminary description of which follows:

(1) Plain pebbles. Total 24. The pebbles vary from 48 mm. to 110 mm. in length. Most are angular but a few are rounded, suggesting that they were collected from the nearby Blaaubank river gravel. With the exception of the chert specimen, all are foreign to the dolomite cave rock and have therefore been deliberately carried to the site.

Materials:		
	Diabase	4
	Quartz	5
	Quartzite	14
	Chert	1

(2) Fractured or damaged pebbles. Total 23. The pebbles vary from 52 mm. to 115 mm. in length. All have been broken in one or more places, but none shows traces of deliberate flake detachment. Thirteen have bruised edges, indicating use as pounders or hammers.

Materials		
	Quartz	12
	Quartzite	10
	Chert	1

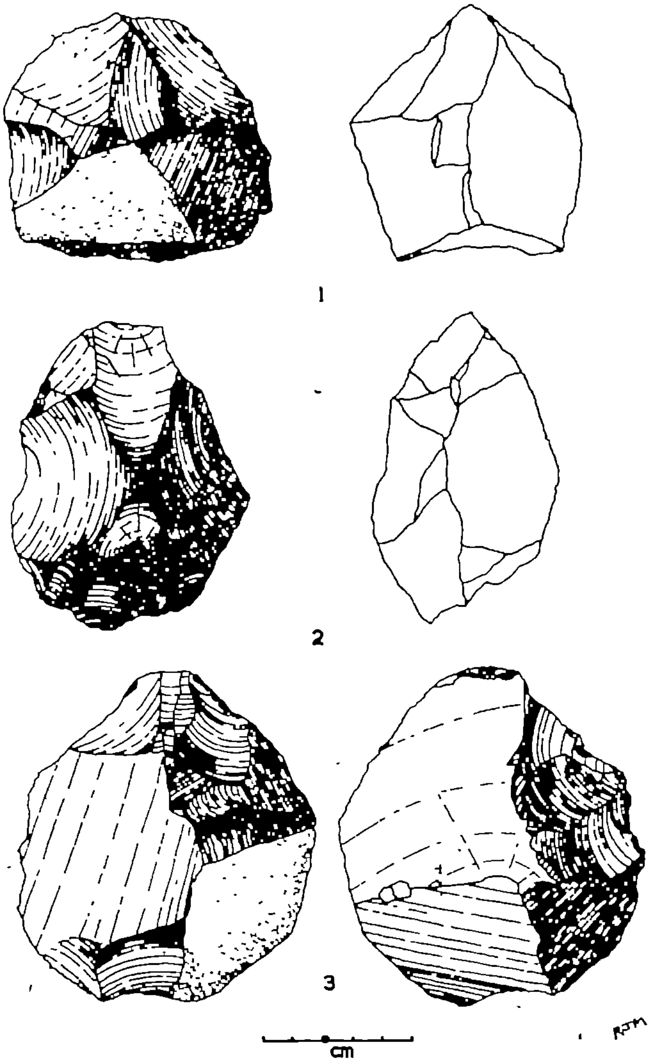

Fig 3

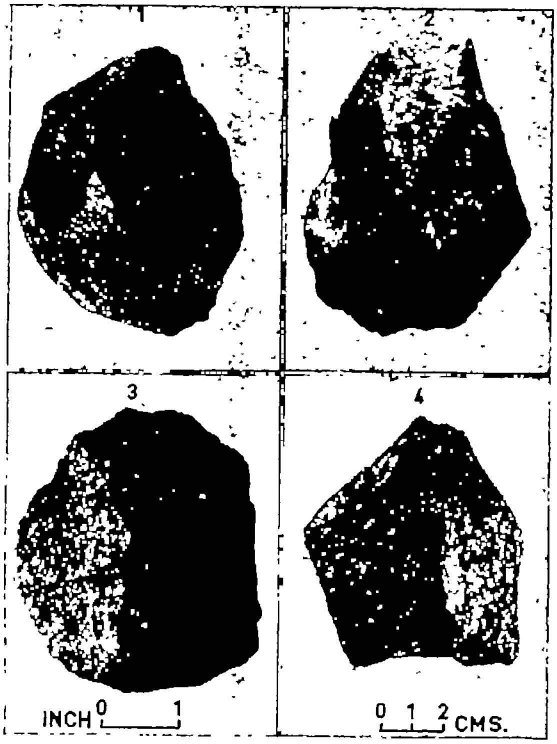

Fig. 4

(1) Broken endstruck flake (see Fig. 2 (1, left))
(2) Core (see Fig. 3 (2, left))
(3) Core (see Fig. 3 (1, left))
(4) Core (see Fig. 3 (1, right))

(3) Prepared hammerstone. One only. The specimen, 82 mm. in length and in diabase, appears to have been deliberately prepared to produce a sharp edge at the intersection of two flaked faces. The sharp edge was afterwards damaged (Fig. 2 (2)).

(4) Endstruck flake. The flake has a length of 110 mm. and thickness of 62 mm. The striking platform is flat, plain and wide, at an angle of 126° to the ventral surface. The dorsal is crudely prepared, cortex covering part of one side. Shallow secondary preparation scars extend along one ventral edge and the dorsal face of the opposite edge. The material is grey fine-grained quartzite (Fig. 3 (3)).

(5) Broken endstruck flake. The flake was struck off a larger quartzite pebble from a cortex platform without preparation, resulting in a cone of percussion. It was then bifacially flaked and one side secondarily trimmed. The original shape is uncertain owing to a broken tip, but suggests a hand-axe-like form. Present length 93 mm., thickness 43 mm. (Fig. 2 (1)).

(6) Cores. Total 8. Lengths vary from 70 mm. to 97 mm. All are in quartzite. Four are on irregular pebbles. The remainder are relatively regular in form. Three may be described as elliptical paraboloid in shape and one as ellipsoid. The elliptical paraboloid form has short wide flakes detached from two faces, one side being left untouched (Fig. 3 (1)). Some workers might classify them as 'choppers'; but, by comparison with later industries where they occur in great abundance, I am reasonably sure they are cores. Some were certainly afterwards utilized as choppers. The ellipsoid form has similar flakes removed from opposite faces on the complete perimeter (Fig. 3 (2)). The irregular cores yielded rough flakes from any convenient face, but did not produce as many flakes per core as the more regular forms. The flake-scars show that the cores yielded small flakes of no regular shape, about 50 mm. × 30 mm. × 20 mm. No trace of the faceted platform technique can be seen. It seems that the flakes were not specially prepared before detachment. After their use as cores, two of the elliptical paraboloid class were utilized as tools.

None of the flakes produced by these cores occurs in the deposit. No core present could have yielded the large flakes described in (4) or (5).

The associated australopithecine remains and stratigraphic position indicate an early date for the industry. It is clear that the industry cannot be assigned to the Kafuan culture if, as is claimed, that culture consists mainly of crudely trimmed pebbles. The more complex, flaking techniques of the Sterkfontein industry show marked similarities to those of the African Chelles–Acheul Stage 1 type series from the Older Gravels of the Klip River at Vereeniging, 76 miles from the site. The flakes, cores and other artefacts could all be found in a Stage 1 series. Some similarities to the Olduvai Bed 1 industry can be observed, especially the utilized cores and hammerstone. While no flakes have yet been described from that bed, some Olduvai Bed 1 cores could have yielded flakes similar to the Sterkfontein specimen shown in Fig. 3 (3).

The Sterkfontein industry is not complete, as the smaller flakes and larger cores are missing. The statistical significance of such a small sample is slight. Making allowance for these factors, it is possible that the Sterkfontein industry occupies a position intermediate between the Kafuan culture and the earliest stage of the African Chelles–Acheul culture. The hand-axe-like tool (Fig. 2 (1)) suggests that future excavations may reveal more advanced tool-types.

The Makapansgat Limeworks site has, like Sterkfontein, yielded australopithecine remains associated with stone tools from a horizon overlying a bed containing more abundant australopithecine remains but no stone tools[3]. Unlike the Sterkfontein industry, the validity of the Limeworks tools is open to some doubt. If the industry is valid, as it might be, it is more primitive in aspect than the Sterkfontein series.

In assessing the relationship of the Sterkfontein industry to the australopithecines, it is necessary to bear in mind the distinction between tool-making and tool-using[4]. There seems every possibility that the australopithecines were capable of tool-using, as Dart's extensive research suggests[5]. It seems that tool-making of the complexity shown in the Sterkfontein industry was probably beyond their ability, and must be ascribed to some more advanced hominid the remains of which are not necessarily preserved in the breccia. The relationships of these early industries will depend on a more comprehensive faunal dating and more representative samples of the industries than are at present available.

NATIONAL WAGE AND SALARY POLICY IN BRITAIN

By Dr. ELLIOTT JAQUES

RECURRING wage disputes, with their bitterness, disruption and inflationary impact, have pointed the need for more effective means of fixing wage- and salary-levels. Discussions of this matter commonly assume that disputes are primarily motivated by employees striving to push their earnings as high as they can, while employers strive to reduce their labour costs. The outcome of the ensuing struggle is held to be determined by the relative bargaining power of the two sides—a power situation the possible mitigation of which was one of the implications of the committee proposed as part of the recommendations in the recent wages dispute in the engineering and shipbuilding industries in Britain.

It may be, however, that it is precisely the assumptions made about collective human behaviour with respect to payment which require re-appraisal, and perhaps elaboration, if we are to order better this aspect of our economic life. For despite the evidence in favour of a predominantly nihilistic view of economic motives, there is also evidence that there exists in each person's mind an idea of a 'fair' rate of payment for the job he does. It is simply not the case that everyone is always agitating for more pay, or changing jobs to get it, or forcing down wages, even when in a position to do so.

This sense of fair payment can be shown to have a firm and objectively definable basis. Further, evidence has been found which suggests that this individual sense of fairness is part of a system of norms of what constitutes a fair rate for a given level of work, unconscious knowledge of these norms being shared among the working population. These observations—which depart from common expectation—have been made by means of a special method for analysing work. Their significance is that they point to a possible empirical basis for a national wage and salary policy based upon equity, and applying to all types of work, from managing director to shop floor.

Payment and Work

The results to be described have come mainly from applied research work carried out over the past eight years in conjunction with a light-engineering concern, the Glacier Metal Company. In the course of this work, it has been found that what is experienced as level or weight of responsibility in a job (which I shall hereafter refer to simply as *level of work*) can be measured by finding the maximum period of time during which the work assigned by a manager to a subordinate requires the subordinate to exercise discretion, or judgment, or initiative, in his work without that discretion being subject to review by the manager. The measure rigorously excludes all those aspects of work which are prescribed or regulated by policies, administrative routines, or physical controls, to which the subordinate must conform or be guilty of negligence. I have termed this measure the *time-span of discretion*; it has been described in detail elsewhere[1].

A maximum time-span of discretion exists in all jobs. Its major significance from the point of view of our present concern lies in the finding that individuals in jobs whose level of work measured in time-span is the same, privately state the same total earnings to be fair for the work they are doing. This finding was independent of income tax paid. I have called the pattern of payment so derived the *equitable work-payment scale*.

Illustrative examples of time-spans and the stated equitable earnings (as of February 1957, the amounts cited tending to change roughly in step with movements in the wages index) are given in Table 1. These figures are based on analyses of some thousand jobs of all types and at all levels, with additional confirmatory findings from a heavy-engineering firm, a food factory, a bank, and a chemical concern. The full scale comprises increments in time-span corresponding to increments ranging from 2 to 5 per cent in stated equitable payment.

Table 1

1 hour	£9 5s. per week
1 day	£10 5s. per week
1 week	£12 10s. per week
1 month	£13 10s. per week
6 months	£950 per annum
1 year	£1,250 per annum
2 years	£2,350 per annum
5 years	£4,750 per annum

When reactions of individuals to their payment are considered in the light of their level of work in time-span, a characteristic pattern of responses can be found. Payment at the equitable level is intuitively experienced as fair relative to others, although there may be a simultaneously held view that the economy as a whole ought to provide a generally higher standard of living for all. Deviations in payment below the equitable level are accompanied by feelings of dissatisfaction which become stronger the greater is the deviation. Deviations at the 10–15 per cent level lead to an active sense of grievance, complaints or the desire to complain, and, if no redress is given, an active desire to change jobs, or to take collective action if an organized group is involved.

Deviations above the equitable level (rare in the current inflationary situation) are accompanied by feelings of being *relatively* well off as compared with others; at the 10–15 per cent level of deviation there is a strong sense of receiving preferential treatment, which may harden into bravado, with underlying feelings of unease about how long the relatively advantageous position can be maintained.

Unstated Assumptions

Use of the time-span instrument has served forcibly to drive home the fact of how easy it is for arguments and disputes about payment to be based upon unwarranted assumptions in the absence of any common level of work referend as to what payment is about. For example, in the case of two stores, one was reputed to pay high wages and the other low wages. Analysis of level of work, however, revealed that in fact the reputedly high-wage paying store had organized its sales work at a higher level than had the other. Its higher pay was for higher responsibility, and the pattern of rates in both stores turned out in fact to be consistent with the pattern of the equitable scale.

How often it occurs, however, that arguments of the above type take place in which comparisons with regard to pay are made between jobs, or different occupational categories, or indeed whole industries or social classes, and in which it is simply assumed that level of work is known. For example, what is a 'reasonable' wage for machine operators as compared with technologists and managers? What ought teachers to earn as compared with skilled craftsmen? Or the middle classes as compared with 'workers'? In the absence of a yardstick—and indeed of any common language even for talking about work—such questions defy systematic resolution.

Many such arguments can be shown to be not only futile, but also misleading. For example, changes can readily take place in jobs which, because they continue to bear the same title, continue to be referred to as the same job. Such comparisons are currently familiar in discussions about the trend of income of 'doctors' as compared with that of 'craftsmen', say, since 1939. The assumption is that the comparative levels of work have remained unchanged. This assumption may be warranted. But it may not be. In the British railway strike in 1955, a similar unrecognized assumption about comparative levels of work remaining unchanged was made in arguments about the comparative trend of earnings of footplatemen and porters since 1905. In this case, in view of the increasingly prescribed character of footplate work, the assumption was most probably not warranted.

In the same vein, supposed payment for scarcity value may not always be what it seems. For more often than not, in my experience, an apparent excess payment in fact turns out to be an increment to bring payment for a job up to the equitable level, in circumstances (common in the expanding technologies) where level of work had been increased without its being recognized, and without a concomitant increase in pay at the time. Until a common yardstick is agreed, it is better to recognize the lack of a yardstick than to argue as though levels of responsibility were clearly and precisely known.

National Payment Policy

Although the foregoing results need to be tested by more extensive studies, their consistency under intensive study in a few widely varying industries suggests the following broad outline of a systematic wage and salary policy. This policy is that of payment for level of work carried in each specific job at any given time. Custom and practice, advantageous position gained through scarcity, social stereotypes about manual as against non-manual types of work—all such criteria would have to be abandoned. Questions of socially necessary income—such as the requirements of those with large families or the needs of men as compared with women—would be matters of government policy, to be dealt with by such mechanisms as taxation and insurance.

This type of policy has two essential features. It rests upon a foundation of the explicit recognition and institutionalized acceptance of objectively discoverable norms of payment in relation to level of work; and it subjects everyone in industry—senior executive and unskilled worker alike—to the same scale of value for the work he does. The burdens of a non-abundant economy would be equitably shared; and increases in national productivity would be reflected in an upward shifting of the whole scale of payment. Individual progress in earnings relative to others could be obtained only by a person's attaining and carrying out higher levels of work—a condition fundamental to the creation of genuine incentive.

Although it is, of course, possible only to speculate, the hypothesis seems warranted that a strengthening of unity of effort to improve the health of the economy might be achieved. This unifying effect would come about from the fact not only that the effects of enrichment or impoverishment of the national economy would be equitably distributed over the total working population including the lowest to the highest paid, but that they could publicly be seen to be so distributed. There is plenty of evidence that absence of objective methods for settling payment-levels in a manifestly equitable manner stirs up widespread envy and mistrust, and causes an abdication of executive leadership, and socio-economic rivalry and stress such as seriously to impede the national recovery.

COMPARISON OF CÆSIUM RESONATORS BY TRANSATLANTIC RADIO TRANSMISSION

By DR. L. ESSEN and J. V. L. PARRY
National Physical Laboratory, Teddington, Middlesex

AND

J. A. PIERCE
Cruft Laboratory, Harvard University, Cambridge, Massachusetts

IN the past few months, we have compared the frequencies of a cæsium resonator at the National Physical Laboratory and an 'Atomichron' manufactured by the National Company of Malden, Massachusetts. The National Physical Laboratory resonator has been described previously[1]. The 'Atomichron'[2] contains a crystal oscillator, frequency-deriving equipment, and a servo that controls the oscillator to maintain a derived frequency in agreement with that of a cæsium beam resonator. An output frequency of 100 kc./s. and others up to 100 mc./s. are provided. Only the lower frequency has been used in this study.

The measurements are made by using the *MSF* standard frequency transmissions[3] as an intermediate reference standard. The *MSF* service operated from

Rugby by the British Post Office on behalf of the National Physical Laboratory includes a transmission at 60 kc./s., and in order to facilitate long-distance comparisons the Post Office has also used the quartz oscillator which controls the frequencies of all the transmissions to control the carrier wave of the *GBR* 16 kc./s. transmitter.

At the National Physical Laboratory the ground-wave of the 60 kc./s. transmission of *MSF* is received and measured in terms of the cæsium atomic standard. The *MSF* standard is also measured in terms of one of the Post Office quartz clocks at Dollis Hill by land line, and this in turn is compared at the National Physical Laboratory with the cæsium standard by land line. In this way it is estimated that the *MSF* 60 kc./s. transmission and the daily average value of the *MSF* standard are both known in terms of the National Physical Laboratory cæsium standard with an accuracy of ±2 parts in 10^{10}.

At Camden, New York, about 400 km. from Cambridge, Mass., the U.S. Air Force is conducting evaluation trials of an aid to navigation, 'Navarho', that involves transmission from station *AF2XKM* at 95 kc./s. with the carrier frequency controlled by a stable crystal oscillator. At the same station there are two 'Atomichrons'. Through the courtesy of the firm of Pickard and Burns, Inc., which is carrying out the evaluation for the Air Force, the transmitted frequency is rated daily in terms of an 'Atomichron', and the results are reported to Harvard. Transmission from Camden to Cambridge is dominated by the ground-wave, so that Doppler effects, when averaged over two or three hours, are quite unimportant.

At Harvard both the *GBR* and *AF2XKM* signal frequencies are measured in terms of a good crystal oscillator. Thereafter, addition and subtraction yield the received frequency of *GBR* with respect to the 'Atomichron'. These values are reported to the National Physical Laboratory.

Unfortunately, these comparisons were begun just as Rugby had to give up day-time transmission because of an aerial maintenance programme. This has limited the precision of these comparisons in two ways: the Doppler fluctuations in night-time transmission across the Atlantic Ocean are larger than those by day; and the various frequency comparisons cannot be made simultaneously, so that vagaries of the frequencies of the various oscillators become important.

The *MSF* signal is measured at the National Physical Laboratory between 20h. and 21h. G.M.T., and the *AF2XKM* frequency is compared with the 'Atomichron' over three or four hours centred at 15h. G.M.T. Because Doppler effects in transmission during the sunrise and sunset hours are serious (about two parts in 10^9 for the trans-Atlantic path) the *GBR* signal must be measured only during the few hours centred at about 3h. G.M.T., when the whole transmission path is in darkness. By measuring *AF2XKM* at Cambridge at the same time, reliance is placed on the Air Force crystal oscillator for interpolation. Alternatively, the oscillator at Harvard may be used for interpolation by measuring *AF2XKM* while that signal is being referred to the 'Atomichron'. Both methods are often used.

There have been many occasions when *AF2XKM* has not operated, or when at least one of the oscillators has been obviously unstable. Results for the dates when all measurements were successfully made are given in Table 1. The results are based on an adopted value of 9 192 631 830 c./s. for the cæsium resonance at zero magnetic field. The corrections for the field actually used are 1 c./s. for the National Physical Laboratory standard and 1·6 c./s. for the 'Atomichron'. The correction of 1 c./s. has been applied to the former results. The actual frequency of the 'Atomichron' is 9 192 631 831·6 c./s., but in order to simplify the electronic synthesis it was assumed to be 9 192 631 840 c./s. A correction of 8·4 c./s. (or 9 parts in 10^{10}) has therefore been applied.

Table 1. DAILY FREQUENCY DIFFERENCES IN PARTS IN 10^9

Date	*MSF* with respect to N.P.L. cæsium standard reduced to 9 192 631 830 c./s.	*GBR* with respect to 'Atomichron'		'Atomichron' with respect to N.P.L. cæsium standard	Monthly average

Mean value, −0·4. Standard deviation of single observation, 0·4

With observations lasting three or four hours, it appears that the measurements of the *AF2XKM* frequency at Camden and at Cambridge can both be made to a very few parts in 10^{11}. Because of the requirement for interpolation, however, we need to

Table 2. Errors in the Measurement of Cæsium (U.K.) versus Cæsium (U.S.A.)

Component of the measurement	Standard deviation in parts in 10^9
AF2XKM relative to 'Atomichron'	0·1
AF2XKM relative to oscillator at Harvard	0·2
GBR relative to oscillator at Harvard	0·3
GBR relative to NPL cæsium resonator	0·2
Resultant	0·4

estimate the stability of the oscillators rather than the measurability of their average frequencies. On one occasion there has been a nearly continuous measurement of the *AF2XKM*-'Atomichron' difference over a period of 72 hr. There was no evidence of diurnal variation greater than 1 in 10^{10}, and the standard deviation was 0·14/10^9. It is not known whether this value was dominated by the instability of the 'Atomichron' or of the crystal oscillator, or both. A similar test of the oscillator at Harvard with respect to *AF2XKM* showed a slightly larger diurnal variation and had a standard deviation of 0·19/10^9. It should be noted that this value includes the propagational effects between Camden and Cambridge. Because there is no marked diurnal variation, we may take the uncertainty due to interpolation as being of the same magnitude as the standard deviations cited above.

The uncertainty caused by propagation of the *GBR* signal across the Atlantic Ocean has been estimated previously[4]. For night-time transmission and a four-hour measurement interval, the standard deviation is expected to be about 0·3/10^9. The various errors, assumed to be uncorrelated, are summarized in Table 2.

This summary value is in agreement with the experimental standard deviation given at the foot of Table 1. Because the errors are determined largely by the transmission variations on the trans-Atlantic path, there is little improvement in accuracy to be expected until day-time transmission is again available. With such transmission, however, simultaneous measurements of suitable duration should give results accurate to at least one part in 10^{10}.

The average difference between the frequencies of the National Physical Laboratory standard and the 'Atomichron' is within the accuracy claimed for the latter. However, one of us (J. A. P.) is confident that the average value of the Doppler shifts in propagation is near zero under the conditions of this experiment; and the others (L. E. and J. V. L. P.) think that it should be possible to construct cæsium standards of the same basic designs as those used in this experiment to agree to ±2 parts in 10^{10}.

The important fact established by the comparison is that two standards completely different in their detailed design can be constructed and operated with such close agreement in widely separated parts of the world.

Two of us (L. E. and J. V. L. P.) would also like to comment that the major part of the work involved in the comparisons was that carried out at Harvard. The measurements made at the National Physical Laboratory are now part of the regular routine adopted in establishing an atomic time-scale and monitoring the *MSF* transmissions.

The work carried out at the National Physical Laboratory is part of the research programme of the Laboratory, and the results are published by permission of the Director. The work in the United States was made possible by support extended to Cruft Laboratory, Harvard University, jointly by the Navy Department, the Signal Corps of the U.S. Army, and the U.S. Air Force, under Contract *Nonr*–1866(07).

NEWS and VIEWS

THE BRITISH ASSOCIATION:

New President

Sir Alexander Fleck has been elected by the General Committee of the British Association for the Advancement of Science as president of the Association for 1958. He will preside over the annual meeting at Glasgow during August 27–September 3, 1958. Sir Alexander, who has been chairman of Imperial Chemical Industries, Ltd., since 1953, was born in Glasgow and educated at Hillhead High School and the University of Glasgow. After graduation he held for a brief period a teaching appointment in the Chemistry Department of the University. Although his first paper was on the analysis of cyclohexane in benzene and was published in conjunction with the late Prof. T. S. Patterson, his important researches at that time dealt with the chemistry of the radioelements, especially those of short life such as radium-A, radium-B and radium-C. His first paper in this field was read to Section B (Chemistry) of the British Association at its Dundee meeting in 1912. His work provided the first experimental demonstration of the validity of the concept of isotopes. Fleck's research activities continued after he joined the Castner–Kellner Alkali Co. during the First World War, and he made an extensive study of anhydrous caustic soda and its behaviour in the presence of sodium metal. This work has not been published. In 1920 the Castner–Kellner Alkali Co. became a subsidiary of Brunner, Mond and Co., and the I.C.I. merger in 1926 gave Fleck's talents wider scope. By 1931 he had become managing director of the General Chemicals Division and six years later was appointed chairman of what is now the Billingham Division. In 1946 the Wilton project was added to his responsibilities and in 1951 he became deputy chairman of the main board. In recent years Fleck has received many honours, including the K.B.E., the fellowship of the Royal Society and three honorary doctorates. It is characteristic of his physique and his restless energy that tree-felling is one of his few relaxations.

Gifts to the Association

SIR GEORGE ALLEN, secretary of the British Association for the Advancement of Science, has announced that, as a result of approaches to a small number of leading industrialists, a very substantial addition to the income of the Association for the next seven years has been obtained. £40,000 has already been received, giving an additional £8,000 income for the coming year. It is now proposed to widen the appeal. Owing to the generosity of this same group of industrialists, it will be possible during the coming year to extend the Association's activities, and detailed plans for the future, which will include inter-meeting activities, are being discussed.

Endeavour Prizes

THE prizes awarded by the British Association for the 1957 Endeavour Essay Competition were presented by Prof. P. M. S. Blackett, on September 5, during the reception for exhibitioners. The competition is sponsored annually by Imperial Chemical Industries quarterly review *Endeavour*, and is limited to those under twenty-five years of age. Seventy-three entries were received, many from abroad, and the prize-winners were as follows: first prize of 50 guineas to Miss Ruth Kirkland, of Sydney, Australia, for an essay on "Particles in Plant and Animal Cells"; second prize of 25 guineas to Mr. R. B. Cain, of Smethwick, Staffordshire, for an essay on "Chemistry and the Conquest of Disease"; third prize of 15 guineas to Mr. Charles Elliott, of Yorkshire, for an essay on "The International Geophysical Year". Two special prizes of 5 guineas were awarded to competitors under eighteen years of age. Mr. Geoffrey Benjamin, of Swansea, won one of these for an essay on "Particles in Plant and Animal Cells". Miss Dorothy Haas, of Birmingham, won the other for an essay on "Chemistry and the Conquest of Disease". An additional special prize of 3 guineas was awarded to Mr. Robin Jones, of Farnborough, for an essay of great merit.

NATURE

BRITISH ASSOCIATION NUMBER

Messrs. Macmillan regret that copies of "Nature" of September 7 were not generally available in Dublin as advertised. The issue was printed and dispatched in good time but delayed in transport through circumstances outside their control

Atomic Energy Authority: Sir Leonard Owen, C.B.E.

SIR LEONARD OWEN, director of engineering and deputy to the managing director of the Industrial Group of the Atomic Energy Authority, has been appointed managing director of the Industrial Group in succession to Sir Christopher Hinton, who has been appointed chairman of the Central Electricity Generating Board. Sir Leonard, who is sixty, has been engaged in the development of Britain's atomic energy programme since 1946, when he was appointed director of engineering on the production side. In the following year he became assistant controller in the Atomic Energy Division's production side. When the United Kingdom Atomic Energy Authority was formed in 1954, he was made director of engineering and deputy managing director.

Sir Leonard was educated at Liverpool Collegiate School and the University of Liverpool, where he obtained the degree of M.Eng. During the First World War he was with the 6th King's Liverpool Regiment, and afterwards was successively with Brunner, Mond and Company and I.C.I. (Alkali), Ltd., with whom he was engaged in the Engineering Department, designing new chemical plant and additions to existing chemical plant. During 1940–45 he was on loan to the Ministry of Supply as Director of the Royal Filling Factories.

University College of North Wales: Dr. R. C. Evans

DR. ROBERT CHARLES EVANS, who has been appointed principal of the University College of North Wales from September 1, 1958, in succession to Sir Emrys Evans, was educated at Shrewsbury School and University College, Oxford, and has, since 1947, held surgical appointments at the Northern, Walton and Southern Hospitals, Liverpool. During 1943–46 he was on active service with the R.A.M.C. and was mentioned in dispatches. In 1953, as Hunterian professor, he lectured to the Royal College of Surgeons on the physiological problems of adaptation to high altitudes. It is as a mountain climber that Dr. Evans is best known to the general public and particularly for his part in the Everest Expedition of 1953, on which he was deputy leader and as 'quartermaster' had responsibility for organizing the stores. On that Expedition he reached the South Summit of Everest, but as leader of the Kanchenjunga Expedition of 1955 he reached the summit except for the last few feet, which, with characteristic consideration for the feelings of the Sikkimese, he left untouched. The conquest of Kanchenjunga is described in his book, "Kanchenjunga, the Untrodden Peak" (1956). Dr. Evans was awarded the Cullum Medal of the American Geographical Society in 1954, the Livingstone Medal of the Scottish Geographical Society in 1955 and the Founder's Medal of the Royal Geographical Society in 1956.

British Institution of Radio Engineers: Awards

THE British Institution of Radio Engineers has recently awarded the following premiums to authors of papers published in its *Journal* during 1956: Clerk Maxwell Premium, to Dr. K. D. Froome (Metrology Division of the National Physical Laboratory) for his paper, "Microwave Determinations of the Velocity of Light"; Heinrich Hertz Premium, to Dr. A. G. Edwards (Associated Electrical Industries, Ltd.) for his paper, "The Effects of Atmospherics on Tuned Circuits"; Brabazon Premium to K. E. Harris, (Director of Research, Cossor Radar Ltd.), for his paper, "Some Problems of Secondary Surveillance Radar Systems"; Louis Sterling Premium to Dr. A. van Weel (Philips Research Laboratories, Eindhoven), for his paper, "Some Remarks on the Radio-frequency Phase and Amplitude Characteristics of Television Receivers"; Marconi Premium to Prof. P. M. Honnell (Washington University, St. Louis), for his paper, "Prescribed-Function Vibration Generator"; Dr. Norman Partridge Memorial Award to H. J. Leak for his paper, "High Fidelity Loudspeakers: the Performance of Moving Coil and Electrostatic Transducers".

Gas Council Research Scholarships

THE Gas Council has awarded research scholarships to the following students who have recently graduated in physics, chemistry or engineering: A. Richmond (University of Oxford, Department of Inorganic and Physical Chemistry), the mechanism of gaseous oxidation processes; K. J. Reid (University of Cambridge, Department of Chemical Engineering), chemical engineering fundamentals; P. Hawtin (University College, London, Department of Chemical Engineering), heat transfer with a special interest in heat transfer to gases; D. Wilson (University of Birmingham, Department of Chemical Engineering), gas absorption; J. N. Sherwood (University of Glasgow, Department of Chemistry), diffusion studies in molecular crystals.

National Vegetable Research Station Association

THE National Vegetable Research Station at Wellesbourne, Warwick, is proposing to form a National Vegetable Research Station Association. The Research Station welcomes contacts with growers. It already owes much to those growers who have assisted in its establishment and subsequent development. The Association is being set up to advance the knowledge, science and practice of vegetable production. Any member (grower or other interested person or firm) will be able to keep in touch with the latest research developments at the Station. He will receive copies of the Station's annual reports and will have the privilege of attending members' days. These days will provide opportunities for the interchange of ideas between research workers and growers, and will enable members to see and discuss work being done at the Station, to keep themselves abreast of the latest progress, and to meet other growers with common interests. Further information can be obtained from the Secretary, National Vegetable Research Station, Wellesbourne, Warwick.

Advice on Careers

ALTHOUGH the Youth Employment Service is performing a useful service in helping school-leavers to find and settle down in the right jobs, the schools have still an important part to play in helping scholars to decide on the kind of career which would be most suited to them. Many teachers are regrettably ill-equipped to give vocational advice, and, to help them, the National Union of Teachers has produced a useful pamphlet. Besides the many advertisements by business, industrial and other organizations—the value of which is open to question—the pamphlet contains a number of notes and articles which are both practical and up to date and should be of considerable assistance to careers masters and mistresses. These include such topics as the employer's expectations from the applicant, the essentials of apprenticeship schemes, universities and admission procedure, the role of the trade unions, careers for girls, selection procedure in industry and commerce and many others. The pamphlet contains exhaustive lists of valuable addresses. Copies can be obtained from the National Union of Teachers, Hamilton House, Mabledon Place, London, W.C.1.

Nature Reserves

FORTY years after its founding, the Society for the Promotion of Nature Reserves has been taking stock. Despite the advent of the Nature Conservancy, the number of inquiries received during 1956–57 from other organizations and individuals interested in the acquisition of Nature reserves shows that the Society still performs an important function. In respect of at least seven of the inquiries discussions are still continuing with interested local individuals and organizations to see whether certain areas can be designated as Nature reserves. The fortieth annual report contains details of how existing Nature reserves are being managed and developed; these vary from Badgeworth Marsh in Gloucestershire, which was acquired solely to protect the very local buttercup, *Ranunculus ophioglossifolius*, to Scotton Common Nature Reserve in Lincolnshire, an area of about forty acres and one of the best of the few remaining tracts of blown-sand heathland in north-west Lincolnshire. Details of all the business transacted by the Society during 1956–57 are contained in the report, which may be obtained from the Society, British Museum (Natural History), London, S.W.7, price 5*s*.

Instrumentation for Gas Chromatography

THE Scott microflame detector has now been made available commercially for gas chromatography (Shandon Scientific Co., Ltd., 6 Cromwell Place, London, S.W.7). This novel detector (Scott, R. P. W., "A New Detector for Vapour Phase Partition Chromatography"; see "Vapour Phase Chromatography", edited by D. H. Desty, p. 131; Butterworth, 1957) depends on the use of a carrier gas containing a considerable proportion of hydrogen, which is burnt in a small flame near the column exit. The presence of an organic vapour in the gas increases the length of the flame, and this results in a comparatively large response from a thermocouple situated just above the normal flame. The advantages of this detector are that it has an extremely small effective volume, resulting in a very rapid response; and secondly, that its response is directly proportional to the calorific value of the vapour; which means that in the analysis of hydrocarbons, calibration of the detector for individual compounds is unnecessary.

A New Submarine Mountain in the Pacific Ocean

A SUBMARINE mountain (31° 34·7′ N., 131° 08′ E.), named after Prof. T. S. Isakov, was discovered by the U.S.S.R. Expedition S.S. *Vityaz* on September 27, 1955 (Sergeev, I. V., and Udintzev, G. B., *Doklady Akad. Nauk., S.S.S.R.*, 113, 1123; 1957). This mountain rests on a 5,000 m. platform and its top is situated at the depth of 1,400 m. Its cone-shaped form and the dredged fragments of volcanic rocks suggest a volcano.

Silvina Estrada de Acevedo Fellowship for Research in Experimental Leukæmia

THIS fellowship, instituted by Don Horacio Acevedo in memory of his wife, for furthering research in experimental leukæmia, is open to scientists from any part of the world who have already been working in this field. It involves full-time work at the Department of Experimental Leukaemia, Blood Research Institute, National Academy of Medicine, Buenos Aires, for one year, from February 1, 1958. The grant may be extended for a second period of one year, should the progress of the investigations appear to justify it. Its value is 5,000 Argentine pesos per month. Applications should be sent not later than November 30 to Fundaleu, Instituto de Investigaciones Hematológicas, Academia Nacional de Medicina, Melo 3081, Buenos Aires, Argentine. Applicants should give details of their educational and scientific qualifications, as well as a programme of the research they intend to do.

Biological Productivity of Britain

On October 4 Lord St. Aldwyn, Parliamentary Secretary to the Ministry of Agriculture, Fisheries and Food, will open, in the Lecture Hall of the Royal Geographical Society, a two-day symposium on "The Biological Productivity of Britain". The symposium is being arranged by the Institute of Biology to discuss the basic productivity of Britain—that of its land and inland waters. The papers to be given will deal with such subjects as the land-use pattern, the factors controlling photosynthesis, the present agricultural production, future improvements in plant and animal production, the production of lakes and of forests, the effect of controlled irrigation, the future of British uplands and finally the production of foodstuffs by unconventional methods. The symposium will be open to all interested. Further information can be obtained from the Institute of Biology, 41 Queen's Gate, London, S.W.7.

Lecture Courses in Nuclear Power

Two courses of lectures on nuclear power are to be given at the Northampton College of Advanced Technology, St. John Street, London, E.C.1. One is a course of twenty lectures entitled "An Introduction to Nuclear Power", to be given on Friday evenings commencing on October 11. The fee for the course is £2. The other course will deal with "The Engineering Design of Nuclear Power Plant", and will be given on Tuesday evenings commencing on October 15. The fee for this course is £1 10s. Further information can be obtained from the Principal of the College.

Institute of Fuel

The following forthcoming meetings have recently been announced by the Institute of Fuel: (1) "Flames and Industry", a one-day Symposium, arranged in conjunction with the British Flame Research Committee of the International Flame Radiation Research Foundation, to be held on October 9, at the Institution of Civil Engineers in London; (2) "Pulverized Fuel", a two-day conference, bringing up to date the report on the Harrogate Conference of 1947, to be held on November 27 and 28, at the Institution of Civil Engineers in London; (3) "Science in the Use of Coal", a residential conference to be held at the University of Sheffield during April 15–18, 1958; (4) the Seventh International Symposium on Combustion, organized in collaboration with the Combustion Institute, a residential Conference opening at the Royal Institution in London on August 28 and continuing at Oxford during August 29–September 3, 1958: (5) "Major Developments in Liquid-Fuel Firing, 1948–1959", a residential conference to be held at Torquay during May 11–14, 1959.

Announcements

The following officers of the Institution of Civil Engineers were elected for 1957–58: *President*, Sir Arthur Whitaker; *Vice-Presidents*, Prof. A. J. S. Pippard, A. O. Hartley, Sir Herbert Manzoni, Sir George McNaughton; *New Members of Council*, A. J. Dickson, F. N. Green, R. le G. Hetherington, E. A. F. Johnston, J. C. Macgregor, H. D. Morgan, T. P. de S. Munasinghe, J. F. Pain, I. W. Pugh, L. G. Smith, N. D. E. Stephens, Dr. Frederick George Thomas.

The Chemical Research Laboratory of the Department of Scientific and Industrial Research, Teddington, Middlesex, is to hold three open days during October 1–3, when visitors will be able to view work in progress. Inquiries should be addressed to the Director.

An international symposium on "Electronic Components" will be held at the Royal Radar Establishment, St. Andrew's Road, Malvern, Worcestershire, during September 24–26. Further details can be obtained from Mr. J. M. Robertson, Visits Office, Royal Radar Establishment.

A course of eight lectures on "Operational Research and Cybernetics" will be given at the Sheffield College of Technology, on Wednesdays, commencing on October 9. The fee for the course is £5 5s. Further information can be obtained from the Registrar, College of Technology, Holly Street, Sheffield, 1.

A conference on "Plasma and Atomic Physics", organized by the Physical Society, is to be held at the Atomic Energy Research Establishment, Harwell, on October 3 and 4. Copies of the programme and application forms can be obtained from the Physical Society, 1 Lowther Gardens, Prince Consort Road, London, S.W.7.

The eighteenth National Conference for the Preservation of the Countryside will be held at Hastings during October 17–19 on the theme: "Rural Problems of the Moment". All inquiries should be addressed to the Secretary of the Council for the Preservation of Rural England, Sir Herbert Griffin, 4 Hobart Place, London, S.W.1.

A conference on "Lubrication and Wear" has been organized by the Institution of Mechanical Engineers and will be held in London during October 1–3. The various sessions will be devoted to hydrodynamic lubrication, boundary friction, boundary lubrication, bearing metals and other materials, ball and roller bearings and special applications. Further information can be obtained from the Secretary, Institution of Mechanical Engineers, 1 Birdcage Walk, London, S.W.1.

A meeting of the Physical Society will be held at 6 p.m. on October 3 in the Physiology Lecture Theatre, Oxford, on the occasion of the presentation of the eighth Charles Chree Medal and Prize to Dr. D. F. Martyn (Commonwealth Scientific and Industrial Research Organization, Australia), in recognition of his valuable work on ionospheric physics. Dr. Martyn will speak on "The Ionosphere as Dynamo and Motor".

TECHNICAL EDUCATION AND INDUSTRIAL TRAINING IN MALTA

THE development of education in Malta has been very slow and, until recently, technical education almost non-existent and industrial training and apprenticeship schemes confined mainly to H.M. Dockyard.

With the grant of internal self-government in 1921, an extensive school-building programme commenced, which much improved the position, but not sufficiently to catch up on the neglect of decades.

Compulsory primary education for all children was not introduced until 1946, when the second period of internal self-government started. But there was insufficient school accommodation, and consequently, in order to cope with the big influx of children, the Government had to introduce a 'two-shift' system by which children received tuition for half-days only.

When the present Government took office in 1955, it immediately gave education top priority in its development plans. It initiated a very large school-building programme, and took over a number of private houses as temporary classrooms. This, together with the recruitment of a large number of temporary teachers, made it possible to abolish the half-time system and provide full-time primary education in 1956.

The Government was determined that the whole education system should be rebuilt from the bottom upwards, and that particular emphasis should be placed on technical education, thus avoiding the mistakes made in some Colonies where education has tended to develop from the university downwards, and too much emphasis has been placed on the grammar-school type of tuition.

The school-building programme has been astonishingly successful, and great credit must go to the Minister of Education herself—the Hon. Miss Agatha Barbara—for her enthusiasm, drive and exhortations. It is no uncommon sight to see Miss Barbara down on a building site spurring on the architects and workmen to greater efforts for the sake of their children.

So far, thirty primary schools and extension blocks have been completed or are in the course of construction; thirteen are in this year's programme (work on some of them has already begun) and thirteen more will probably be started next year. A technical school for a thousand boys will be completed in a few months time, work has just started on a technical school to house a thousand girls, and a second boys' technical school and a secondary modern type of school for boys will be started next year. Another three years will see the end of the present primary school-building programme.

At the moment only 9 per cent of primary school leavers are able to get any sort of secondary education. The present school-building programme, together with the Government-financed extension to St. Patrick's Technical School, will increase this to 20 per cent: 10 per cent to grammar and secondary modern, and 10 per cent to secondary technical schools.

Nor are the other aspects of development being neglected. The output of the local teachers' training colleges has been stepped up, and teachers are being recruited from overseas for short periods, while Maltese teachers and students are being sent overseas for further education. Unfortunately, the Royal University of Malta has no Education Department.

The hitherto backward state of education has been an important factor contributing to the under-development of the Maltese economy. This has necessitated large-scale emigration, which has deprived the country of its more virile, adventurous and skilled workers, and created an unbalanced population structure: that is, an excess of 20,000 women over men, and fewer and fewer able young working men having to support a proportionately larger number of old people, women and children. This in turn has retarded development and created a feeling of apathy and despair.

There was obviously only one solution: to make a determined effort to develop the economy, particularly through industrialization and the expansion of the tourist industry. One of the pre-conditions of any development was a thorough reform of the whole educational system. Thus the Government's educational development programme was designed, not only as a social service providing the intellectual, moral and spiritual training of children for adult life, but also as an important part of an imaginative programme designed to lift the Maltese economy from its depressed state and increase the standard of living of her people.

It is clear from the very start that since the development of technical education was going to take some years, something must be done immediately to provide some sort of technical and industrial training for the unemployed—from whose ranks so many of the juvenile delinquents emerge—for prospective emigrants and to provide sufficient qualified technicians to carry out the five-year development programme.

With the co-operation of the International Labour Organization, which provided the technical advice and technical teachers and supervisors, and also the British Government, which provided a special grant of £400,000 out of the Colonial Development and Welfare Fund in addition to other funds, the Maltese Government started training courses in January 1956. An old tram depot was taken over and adapted, and since then a classroom block and new workshops have been added, with further accommodation being provided on the sister island of Gozo.

The original six-months course has been extended to ten months, and in the case of lads between sixteen and eighteen it is now being further extended to three years, to enable the boys to sit for examinations of a recognized high standard. Attendance is full-time, and an attendance allowance ranging between 30*s*. and 50*s*. a week is being paid. The training includes the teaching of theory and practice of each trade; in addition, English is taught.

The centres have already turned out 300 trainees, including a very valuable 150 electrical wiremen who were immediately absorbed by Government departments and private contractors on the change-over of the electricity distribution system—a project originally scheduled to take more than four years, but now in process of being speeded up to be completed by the end of 1958. Most of the trainees have obtained good employment in Malta, or have emigrated.

At present there are 325 young men receiving full-time training in the following trades:

Course	Malta	Gozo	Total
Woodwork	45	24	69
Motor mechanics	45	15	60
Electrical installation	98	—	98
Plumbing	30	—	30
Painting	15	—	15
Sheet metal work	15	—	15
Plastering and tile-laying	15	—	15
Fitting and machining	13	—	13
Concrete supervisors	10	—	10
	286	39	325

Other courses are shortly being started for the training of agricultural workers and for women in homecraft, hotel duties, handicrafts, etc. In addition, a new scheme is being devised, in collaboration with the British Ministry of Labour, for the further practical training of trainees in factories in the United Kingdom.

Thus it can be seen that the whole of the Government education programme is designed to meet the economic requirements of the Islands, while providing for the individual and social development of young people, so that they can lead a fuller and richer life, either in Malta or overseas. The industrial training courses have given new hope to the youths who received only a bare primary education and then joined the ranks of the unemployed (and often became juvenile delinquents); as secondary education is developed, fewer youths will find themselves in the position in which the young men now enjoying these training courses were once placed: the position of being half-educated, unemployed or unemployable, frustrated and without any aim in life.

INTERNATIONAL CONGRESS OF PSYCHOLOGY

THE fifteenth International Congress of Psychology was held at Brussels during July 27–August 3, under the patronage of King Baudouin of the Belgians. The Congress was organized by the Belgian Society of Psychology under the auspices of the International Union of Scientific Psychology founded in 1951 at the thirteenth Congress, held at Stockholm. The Union has consultative status with Unesco, and now represents twenty-six national psychological societies. More than a thousand persons attended the Congress from some thirty countries, including about two hundred from the United States and many representatives from the U.S.S.R., Poland, Hungary, Czechoslovakia and Rumania. The homogeneity of the assembly was tempered by a sprinkling of neurologists, psychiatrists, physiologists, ethologists, educationists and philosophers.

Inaugural addresses were given by M. Léo Collard, the Belgian Minister of Education, Prof. Jean Piaget, president of the International Union of Scientific Psychology, Prof. Otto Klineberg, secretary-general of the Union, Prof. Albert Michotte, president of the Congress, and by Prof. Henri Piéron, of the Collège de France. These were followed by Prof. Michotte's presidential address, "Reflexions on the Role of Language in the Analysis of Perceptual Organization", in which he emphasized the importance of distinguishing, first, the verbal report given by an experimental subject; second, the experimenter's interpretation of this report; and third, the theoretical construction which the experimenter places upon his own interpretation. The relevance of this threefold distinction was illustrated by reference to Prof. Michotte's classical experiments on the 'perception of causality'. Evening discourses were delivered by Prof. Wolfgang Köhler on "Psychologi- und Naturwissenschaft", by Prof. Jean Piaget on "The Role of Models of Equilibrium in Psychological Explanation", and by Prof. Clyde Kluckhohn on "Psychology and Anthropology".

The programme consisted of symposia, individual papers and colloquia on some twenty-six themes. These included such traditional topics as phenomenology, the measurement of sensation, perception, learning, thought, emotion and conflict, motivation, the experience of space and time, biochemical influences on behaviour, brain and mind, and problems of psychological linguistics. The march of time—even in psychology—was recorded by the inclusion of such topics as non-parametric structural analysis, information theory and its psychological applications, and automation. Individual papers covered an even wider territory ranging from "The Impact of Education on Non-Scientific Beliefs in Ethiopia" to "Phantom Limbs". The three colloquia, to which selected participants were invited, were concerned respectively with the training of psychologists, terminology and co-operation with neuropsychiatrists. Psychologists from universities and research and other establishments in Great Britain contributed their fair share to the proceedings. They took part in fifteen out of the twenty-four symposia and were responsible for organizing six of them.

Informal discussions between individual members of a congress can be at least as stimulating as listening to formal lectures, and apart from such informal discussions, there were opportunities for planning and co-ordinating new research. The meeting at Brussels made possible a multitude of invaluable exchanges of this kind and, of course, many new scientific contacts were established. One noticed particularly the keen mutual interest which psychologists from the United States and the U.S.S.R. expressed in work in their respective countries. Unfortunately, many American psychologists, especially those working in military establishments, do not seem to be in a position to propose making professional visits to research institutions in the U.S.S.R. A Russian suggested that they might overcome their difficulties by going as tourists.

It would be an invidious as well as an impossible task to single out the most noteworthy contributions, and I shall not here betray my own bias. Although the old 'schools of psychology' seem to be more or less extinct, psychologists are still sharply divided in the basic conception of their subject as well as in the nature of their work. Nevertheless, anyone with sufficiently broad interests could have profited from participation in most or even all the symposia. No epoch-making discoveries or Copernican revolutions appear to have been announced. Psychologists nowadays seem to be mostly content with modestly describing their day-to-day research, though some are wedded to theories of their own construction and devote their lives to searching for data to fit them.

Something should be said about the wider problems of conducting a congress of this kind successfully, that is, in such a manner as to ensure that lack of familiarity with the language of the speakers, poor acoustics and administrative blind spots do not add to the task of communicating a highly compressed technical report in a short interval of time. No facilities for simultaneous translation of the papers were available because of the prohibitive cost. Consequently, a number of participants—how many it is hard to say—failed to appreciate the papers in spite of possessing a good reading knowledge of the languages in which the papers were delivered. So much so that a proposal was submitted to the president by one member that an investigation be undertaken of the intellectual effectiveness of the Congress. In these days when numerous international congresses are held in science, technology and medicine, the results of a study of this kind might well prove to be of widespread interest. Similar studies have been sponsored in the past by the World Health Organization and Unesco[1].

Many of those who had attended international congresses of psychology on previous occasions doubtless felt that the scientific quality of the contributions and discussions marked a distinct advance. The eccentric fringe which used to be attracted to international assemblies of psychologists was happily small; apart from one or two with highly characteristic opinions of their own, the mass of the members were indistinguishable from any other body of intellectual workers. All of them will recall with pleasure the reception at the Hôtel de Ville given by the Mayor of Brussels, and the paternal devotion lavished on them by Prof. Louis Delys, secretary-general of the Congress.

The Congress was preceded by a two-day international symposium on 'military psychology', held at the Palais des Académies and sponsored by the United States National Academy of Sciences and National Research Council at the request of the United States Air Force, Air Research and Development Command.

JOHN COHEN

SOLVENT EFFECTS AND REACTION MECHANISM

FOR some years the Department of Chemistry of Queen Mary College, London, has organized symposia on the mechanisms of organic reactions. This year the specific topic of discussion was the effects of changes in medium on chemical reactions in solution. The meeting was held under the auspices of the Chemical Society on July 8 and 9. The title of the symposium was interpreted very broadly by both the organizers and the speakers, and the subjects ranged from organic chemists' investigations of reaction products to a thermodynamic treatment of solutions. Sixteen papers were read; eight of them came from the United States, seven from British laboratories, and one from a Swiss laboratory.

The first session, under the chairmanship of Prof. E. D. Hughes, was largely concerned with the mechanisms of organic reactions. The first paper, by Prof. P. D. Bartlett of Harvard University, dealt with the relation between reaction-rates and solvent properties in terms of the short-range interactions between solvent molecules and the reactants and transition states. Prof. Bartlett brought out very clearly the inadequacy of any treatment which considers only the bulk dielectric constant of the solvent, but showed how the kinetic effects of graded changes in solvent properties, for example, acidity or deuterium content, could sometimes be used as mechanistic criteria. The hydrolysis of β-lactones was discussed in this context. Discussing this paper Prof. W. F. K. Wynne-Jones pointed out that the kinetic effects of changes in bulk dielectric constant will be of considerable importance for solvents of low dielectric constant. He also gave examples of the effects of solvent changes on acid-base equilibria.

The nature of solvolytic reactions the behaviour of which may be intermediate between S_N1 and S_N2 was discussed by Dr. V. Gold of King's College, London, with particular reference to the ways in which solvent molecules can interact with the reaction centre. The range of the subsequent discussion showed that there is no unanimity of opinion on this particular problem. It appears that the original definitions of Hughes and Ingold are sometimes used rather loosely, and their appropriate application limits considerably the territory in this 'no-man's land' between the two clear-cut mechanisms.

Dr. E. M. Kosower of the University of Wisconsin described the dependence of the charge-transfer spectrum of some alkyl-pyridinium iodides upon solvent composition. This dependence could be used for calculating an empirical measure of solvent polarity, the Z value, which could be correlated with the rates of some solvolytic reactions. Evidence on the nature of the carbonium ion intermediates in reactions and oxygen exchanges of some alcohols and glycols was given by Dr. C. A. Bunton of University College, London. The carbonium ions may be captured by water molecules, regenerating the original alcohol, and this is observed in the elimination of olefins, and in anionotropic rearrangements.

The kinetic effects which deuterium substitution on a β-carbon atom has on nucleophilic substitutions and eliminations were described by Dr. V. J. Shiner of the University of Indiana, and various explanations of these effects, involving *inter alia* solvent interactions with the polarized C—H or C—D bonds, were considered. Discussing this paper, Drs. Halevi and Lewis gave further evidence for the thermodynamic and kinetic effects of deuterium substitution.

The mechanisms of solvolyses of carboxylic acid amides and esters in sulphuric acid were then discussed by Dr. R. J. Gillespie of University College, London. These compounds are fully protonated in this highly acidic solvent, and unimolecular mechanisms are facilitated, whereas in water and aqueous-organic solvents bimolecular substitutions are more common.

Prof. W. F. K. Wynne-Jones of King's College, Newcastle upon Tyne, was the chairman for the morning session of July 9. The first paper, by Dr. M. L. Bender of the Illinois Institute of Technology, was on the catalytic effect of Bronsted bases on the hydrolysis of esters and amides, and the evidence given showed that they acted as nucleophilic reagents by attacking the carbonyl carbon atom, creating entities which readily undergo further reaction. The catalytic power was much greater when these nucleophilic groups were already present in the molecule, and it was suggested that this catalysis might occur in some enzyme-catalysed hydrolyses.

The next three papers dealt with the intimate details of the interactions between solvent and solute molecules. Dr. P. A. M. Wyatt of the University of Sheffield discussed the possibility of accounting for the properties of a solution in terms of a specific or 'chemical' solvation. He quoted as examples the thermal properties of solutions in sulphuric and nitric acids, and pointed out that, although solvation is important, other factors have to be considered, and that their nature is not well understood. Dr. J. W. Smith of Bedford College, London, showed how measurements of dielectric constant can give evidence for hydrogen-bonding in liquid mixtures, and how steric hindrance in aromatic amines could affect their interaction with solvent molecules. A semi-empirical treatment for the dependence of the rates of nucleophilic substitutions upon solvent properties was outlined by Dr. R. F. Hudson of Queen Mary College, London, who applied this treatment to the kinetics of alcoholyses of acyl halides in solvents of low polarity.

Spectrophotometric methods for investigation of carbonium ions in non-aqueous solvents were described by Prof. A. G. Evans of University College, Cardiff. His group has studied the formation of these ions from triaryl compounds, and it seems that there are specific interactions between the phenol molecules of the solvent and the carbonium ions. Similar measurements have been made on the carbonium ions formed by protonation of an olefin, or by the reaction between an alkyl halide and a metal halide. During discussion of this work Dr. R. H. Plesch suggested that these spectrophotometric measurements could be used to calculate approximate values for the solvation energies of carbonium ions.

The chair was taken by Prof. M. S. Newman of the University of Ohio during the afternoon session. An electrostatic theory for the kinetic effects of solvents was presented by Prof. E. S. Amis of the University of Arkansas, who suggested that the rates of many reactions could be correlated simply with the bulk dielectric constant of the solvents. Subsequent speakers showed that this simple electrostatic theory could not account for many of the complex solvent effects on rates and equilibria.

Dr. H. Zollinger read a paper by himself and Dr. O. A. Stamm on the kinetics of diazo-coupling reactions studied in the University of Basle. They found that kinetic salt and solvent effects could only be considered in terms of specific interactions between ions or solvent molecules and the groups present in the reactants. The authors were able to interpret the effects of Brönsted bases on the rates and chemical course of these reactions by considering their mechanistic details.

The first of two papers on solvent effects in non-polar reactions was given by Dr. J. E. Leffler of Florida State University, who outlined the form of the interactions between ions or solvent molecules and the reactants and transition states, and described a very detailed kinetic study of the rates of racemizations of a number of optically active diphenyls. Dr. G. A. Russell of the General Electric Corporation gave results on the photochemical chlorination of aliphatic hydrocarbons in conditions such that the first step of the reaction is the abstraction of a hydrogen atom from the hydrocarbon. It was possible to use the variation of product composition with changes in the solvent as evidence for the formation of a complex between an electrophilic chlorine atom and an aromatic hydrocarbon. In discussing this work Dr. W. A. Waters showed that while some free atoms and radicals had electrophilic properties others, such as sodium atoms, could act as nucleophilic reagents. The paper by Prof. L. F. Hatch and his co-workers described a re-investigation which they had made of the products of the addition of bromine to butadiene in various solvents.

The wide range of work discussed at this symposium shows the interest which chemists are taking in the effects of solvent composition upon rates and mechanisms. Understanding of the short-range forces which govern the interactions between solvent molecules and solutes during the collisions in which chemical reactions occur is now needed. It was therefore unfortunate that the recent work on nucleophilic substitutions in benzene, a solvent in which these interactions have been studied, was not one of the subjects under discussion.

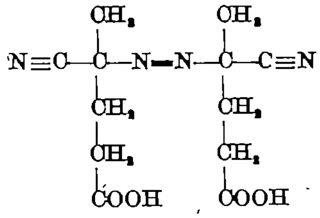
C. A. BUNTON

BLOCK AND GRAFT COPOLYMERS

CONTINUING earlier seminars on polymer science in the Chemistry Department of University College, London (cf. *Nature*, 178, 18; 1956), five lectures on block and graft copolymers were given on July 15.

Prof. M. Szwarc (Syracuse University, New York) described experiments which show that anionic polymerization of certain vinyl monomers, such as styrene, carried out under appropriate conditions, does not involve a termination step (cf. Szwarc and collaborators, *J. Amer. Chem. Soc.*, 79, 2026; 1957; and references to earlier communications given there). Polymers, formed in this manner, are able to continue their growth, if a fresh portion of monomer is added, after the complete conversion of the original monomer. If a monomer, *B*, is added to a block of 'living' polymer *A* . . . *A* a block copolymer is formed. The original polymer *A* . . . *A* may possess one or two 'living' ends, and therefore a variety of block copolymers can be prepared by relatively simple experimental techniques. The interaction of 'living' polymers with proton donors, carbon dioxide and oxygen was shortly discussed.

Dr. C. H. Bamford (Courtaulds, Ltd.) described a method for the preparation of block copolymers. A monomer, *A*, carrying a tertiary base residue, is converted into a polymer,  $A\ldots A\text{—}\overset{\text{Me}}{\underset{\text{N(Et)}_2}{\text{C}}}\text{—H}$, which is afterwards used as a macromolecular transfer agent in the polymerization of a second monomer, *B*. Chain transfer to the terminal group of the first polymer results in the formation of a block copolymer  $A\ldots A\text{—}\overset{\text{Me}}{\underset{\text{N(Et)}_2}{\text{C}}}\text{—}B\ldots B$. In a second method for preparing block copolymers, use is made of the following chain initiator:



$N{\equiv}C{-}C(CH_3)(CH_2CH_2COOH){-}N{=}N{-}C(CH_3)(CH_2CH_2COOH){-}C{\equiv}N$

which leads to polymers containing terminal carboxyl groups. These latter species are coupled together by diols or other suitable bifunctional reagents. These two techniques were successfully applied for the preparation of block copolymers containing methylmethacrylate and either acrylonitrile or styrene. The composition and size distribution of some of these block copolymers could be calculated.

Drs. P. W. Allen, G. Ayrey and D. T. Turner (British Rubber Producers Research Association) gave lectures dealing with graft copolymers (I), made from natural rubber and polymethylmethacrylate. The copolymer (I) was prepared by the polymerization of methylmethacrylate, initiated by γ-radiation, this reaction being carried out in the presence of natural rubber. The influence of the purity of the natural rubber and of the methylmethacrylate, field intensity, concentration of methylmethacrylate and other variables on the rate of formation, yield and structure of the copolymer (I) were investigated. An alternative method of preparing the copolymer (I) consists in the benzoylperoxide initiated polymerization of methylmethacrylate, this process being again carried out in the presence of natural rubber. If azoisobutyronitrile is used as initiator, polymethylmethacrylate is formed, but no copolymer (I). The cause of this specific initiator effect and some aspects of the mechanism have been investigated by using initiators labelled with carbon-14. In these investigations the separation of copolymer (I) from the natural rubber and methylmethacrylate was carried out by fractional precipitation, fractional extraction and turbidimetric titration methods. For purposes of characterization of (I) its molecular weight was determined, and after degradation of the rubber component with ozone, the molecular weight of the remaining polymethylmethacrylate component was measured.

ELECTRONIC INSTRUMENTS EXHIBITION, MANCHESTER

THE Institution of Electronics is a nation-wide organization, but its headquarters are now in the north of England and its main centre of activity is Manchester, where the exhibition of electronic instruments organized by the Northern Division has, since the War, become established as an annual event. The twelfth annual Electronics Exhibition and Convention was held during July 11–17 at the Manchester College of Science and Technology. About sixty manufacturers and other organizations exhibited their products, and the Exhibition was attended by about 14,000 visitors. Most of the exhibits consisted of commercially available equipment, which was in some cases shown in action, and there was also a special section for equipment still in the research stage. A programme of lectures and films ran concurrently with the Exhibition, and these were well attended.

Earlier Exhibitions have included a number of sections which would appeal to a wide public—for example, sound-reproducing equipment and electronic musical instruments. However, these were absent from this year's Exhibition, which was clearly aimed, even more than usual, at the professional user, and perhaps the manufacturer, of electronic instruments. For the latter, components and even such things as racks and chassis were shown by several firms. The Exhibition included an impressively wide range of instruments, of which a few only, a personal selection, can be mentioned. There was, in any event, little that was really new, although there were some items which had appeared since last year's Exhibition.

A flying-spot microscope which was shown by Cinema-Television, Ltd., is fitted with arrangements for counting the number of particles in its field, and their size distribution is obtained by successive counts with different adjustments of a size discriminator. A magnetic 'memory' in the counting unit ensures that a particle large enough to be scanned on several successive lines is only counted once: this is only defeated by particles the shape of which is re-entrant in the scanning direction, or perforated.

Another exhibit by Cinema-Television, Ltd., was a photographic contact printer designed to produce satisfactory contact prints from patchy negatives. A rather large spot of light from a cathode-ray tube scans, raster-wise, the negative with the printing paper in contact. The light passing through them both falls on a photocell the output of which is used to produce limited variations in the brightness of the spot. The broad scanning lines produced by the large spot overlap considerably, so that the definition is that of the negative and no scanning lines appear on the print. The instrument, in fact, carries out automatically the hand-shading usually employed in the printing of uneven negatives. Its cost, more than £900, will presumably limit it to large-scale users, and examples were given of its use in connexion with aerial photography and the commercial printing of amateurs' negatives. Another version which will make enlargements is to be produced.

An exhibit which was at least new to these Exhibitions was a version of the Land camera made by Langham Thompson, Ltd. In its present form it is intended for photographing cathode-ray tube displays and is fitted with an $f/3{\cdot}5$ lens and a single-speed shutter. The novelty is that instead of film it uses special photographic paper with pods of developing and fixing chemicals attached to it at regular intervals. When the paper is wound on after exposure, rollers burst one of the pods and the chemicals are spread on the paper while it is still inside the camera. After waiting for one minute the paper is pulled out and emerges as a finished positive print. The material available is very fast (35° Scheiner) and some twice as fast is promised soon. The operating cost is about 2*s.* 6*d.* a print (4 in. × 3 in.).

Of the many cathode-ray oscilloscopes on show, the most novel were probably those by Cossor, Ltd., which are available only as kits of parts, but at little more than half the cost of comparable finished instruments. They use printed circuits throughout, and the made-up samples on show were clean-looking jobs—in fact, one suspects that the relative absence of wiring will greatly reduce the tangled web which sometimes results from amateur construction, as well as making the circuit characteristics more predictable.

Three kits are at present available, for single-beam and double-beam oscilloscopes and for a valve voltimeter.

Several counting and scaling units were shown—one which provided some relatively light relief was arranged to measure one's reaction time. The victim was required to press a button when some miniature traffic lights turned red. The time taken in microseconds was duly counted and displayed; it was usually of the order of 2×10^5.

The research section showed a change from previous years in that there were no university exhibits, but three by national organizations: the Admiralty, Atomic Energy Research Establishment, Capenhurst, and the British Railways Research Department. The last-named was showing a train control system which automatically applies the brakes of a train passing a signal at danger. The Hall effect in an indium antimonide probe attached to the train is used for detecting the energization of an electromagnet between the tracks. This equipment, which is still in the experimental stage, is intended as an all-electronic successor to the electro-mechanical system now going into service.

J. E. GEAKE

ENGINEERING TRAINING IN THE BRITISH BROADCASTING CORPORATION

THE series of B.B.C. Engineering Monographs, to which reference has already been made in *Nature* (177, 519; 1956), provide a continuous description of the technical equipment and operation of the Corporation, developed and applied to the conduct of its duties as a public broadcasting authority. Among these duties is that of recruiting and training the large numbers of engineers and technical personnel required by the organization.

B.B.C. Engineering Monograph No. 11* is entitled "Engineering Training in the B.B.C.", by Dr. K. R. Sturley, and this describes the work of the training department which came into existence about eleven years ago, and is established at Wood Norton Hall, Evesham. Here there is accommodation for up to two hundred residential students, and full teaching facilities during various courses of instruction, which vary in length from one or two up to twelve weeks. The aims of the training department are to develop the skill and capabilities of staff, to encourage them to adopt a constructive attitude to new ideas and to increase the efficiency of the individual to the mutual benefit of himself and of the organization to which he belongs. Every attempt is made to avoid duplicating the basic training in electrical engineering which is provided by universities and technical colleges; the department concentrates on the application of basic principles to the equipment and methods used in broadcasting.

Some of the courses provide training for newly recruited entrants to the operating and technical assistant staffs, where the instruction varies from the arrangement of studio lighting to the maintenance of high-power transmitters. More advanced courses are intended to provide junior staff with opportunities for promotion in the operations or maintenance fields. Students with the appropriate national technical qualification may be exempt from the first part of this course; they are then required to take the second part, dealing with broadcasting equipment and technique which cannot be a part of the syllabus leading to an academic award. At a more advanced level there is a graduate apprentice course of two years duration, involving attachment to other departments of the B.B.C. as well as the training department. Its purpose is to produce a well-balanced man of wide experience, who will eventually qualify for corporate membership of his appropriate professional institution. Two types of graduates are sought here: one intended for specialist departments such as those conducting research or design and development; the other is intended to fill a senior position in the operation and maintenance branch, where the ability to supervize staff and to deal coolly and efficiently with an emergency are essential qualities.

Under Dr. Sturley as head of the Training Department, the instruction is organized in four sections dealing with fundamentals, radio-frequency transmission, studio and recording techniques, and operations; a fully qualified staff of lecturers, demonstrators and laboratory assistants is provided. A separate section of staff is responsible for the production of training manuals, and also of booklets on such subjects as television lighting, frequency modulation and slot aerials, which are of great value to the technical staff of the Corporation.

During July 22–26 last, a summer school was held at Wood Norton and was attended by some thirty members of the staffs from the engineering and physics departments of universities and technical colleges in the United Kingdom. In addition to inspecting the Training Department and witnessing demonstrations in the laboratories, a series of lectures was given by members of various departments of the B.B.C., the subjects ranging from training, research and operation to the presentation of science in sound and television broadcasting. The programme naturally included talks on the engineering and technical requirements of the B.B.C. staffs, and there was ample opportunity for both formal and informal discussion between the visitors and the resident staff. This short and very successful summer school, which was a repetition on an expanded scale of one held in 1952, should do much to strengthen the ties between the Corporation and the colleges on which it must rely for its recruits.

TRAINING OF FACTORY WORKERS

THE effectiveness of the training of factory workers has an important bearing on industrial productivity. Developments of production methods in this century, particularly in some of the newer industries, have made it possible to employ large proportions of semi-skilled and unskilled workers in the factories; the training of this kind of operative has been relatively neglected until recent years, presumably on the assumption that, because his work was simple in comparison with that of the craftsman, he would be able to learn it with a minimum of assistance.

---

* B.B.C. Engineering Monograph No. 11: Engineering Training in the B.B.C. By Dr. K. R. Sturley. Pp. 24. (London: British Broadcasting Corporation, 1957.) 5s.

That this is an unwise policy to follow has been demonstrated by the experience of firms which have set about the training of semi-skilled and unskilled workers in a systematic fashion, endeavouring to teach them the knowledge and the skills they have to acquire in order to carry out their work effectively. In order to encourage industry to recognize the importance of the subject and to help managers with information on the training of operatives, the European Productivity Agency sponsored a survey in seven European countries. The aim of the survey was to study current practice in the systematic training of operatives within the factory itself.

The organization responsible for the survey in Britain was the National Institute of Industrial Psychology, which was also made responsible for co-ordinating the whole inquiry and preparing a report*.

The survey made it abundantly clear that, as yet, industry in general has done very little to provide training for semi-skilled and unskilled workers on a systematic basis. The situation differs from industry to industry; it was easier to find examples of systematic training in the textile and clothing industries, in the electrical and transport equipment industries and in the chemical industry than in others.

The fact that systematic training is so little developed reflects the attitude of managers to the question of training for the kind of work with which the inquiry dealt. This attitude seems to stem from a number of ideas, to four of which reference was most frequently made.

The first was that semi-skilled and unskilled jobs were so simple that they could easily be learned without any training. Secondly, there was the fear that workers who were trained would be enticed away to other firms, perhaps at higher wages. An associated idea was that, because the rate of labour turnover was high, it was not worth while attempting to improve the training of the new workers. Lastly, there was the notion that systematic training is necessarily elaborate and expensive. This stems from the lack of information on training methods and their applicability to different kinds of situation, with their relative advantages and disadvantages.

There were, however, some managers who considered that they had a social responsibility for ensuring that their employees were helped to acquire the knowledge and the skills needed for the successful execution of their work. Some took a still wider view of their responsibilities: it was not, they felt, enough for industry to help the individual to develop his professional skill; it should provide him with opportunities and assistance for developing general knowledge and character qualities which would help him to lead a fuller and more satisfying life.

Although no evaluation of training schemes was possible because firms were not in a position to provide the evidence on which such an evaluation could be based, it was the almost unanimous opinion that the results were beneficial.

The survey also demonstrated the general applicability of systematic training methods in factories. Not only were the learners of all ages, but also the range of unskilled and semi-skilled jobs for which training was being given was a very wide one, from tasks as simple as machine feeding or packing articles in boxes to others like weaving and loom maintenance, where both the knowledge and the skill involved can be extensive.

In all countries the investigators reported a tendency for training schemes to be weaker on the side of instructional method than on that of organization. In many cases those who gave the instruction to the novices had not themselves received any training in the art of instruction. Although success in instruction is largely dependent on the personality of the instructor and his interest in the job, skill in instruction can be developed by formal training, and an increase in facilities for such training will be required in all the countries concerned as the systematization of training of semi-skilled workers is extended in industry.

COLONIAL TERRITORIES

REPORT FOR 1956–57

THE report on the Colonial territories for 1956–57* follows the pattern of previous years, providing the conspectus of political, economic, financial and social developments in these territories against which the achievements to be recorded in greater detail in "Colonial Research, 1956–57" are to be considered. Some of this material, outlined in the chapter entitled "Research and Surveys", has also appeared in reports from various Colonial research organizations already noted in *Nature*, and for this reason, although this chapter of the present report is that of most direct interest to the scientist, consideration of research in the Colonial territories will be deferred until the fuller report on "Colonial Research, 1956–57" is published in due course.

Recruitment to the Overseas Civil Service was maintained generally at the level of previous years. Almost the same number of electrical and mechanical engineers were recruited as in 1955, and recruitment of civil engineers improved; that of agricultural officers fell. Demand remained high for all these appointments, and there was little change in the number of unfilled vacancies. Those in the service of Colonial governments who received training in the United Kingdom reached a record number of 2,752, compared with 2,190 in 1955 and 2,081 in 1954.

Outputs of most products rose in 1956 and it is estimated that the gross domestic product at market prices in the Colonial territories was some 4 per cent higher than in 1955. Increases in cocoa production in both the Gold Coast and Nigeria largely compensated for the lower prices. In 1956 roughly half the United Kingdom's imports of hardwoods came from the Colonial territories. A new copper smelter and textile plant were opened in Uganda, and a large expansion in bauxite production is planned in Jamaica and British Guiana. The value of Colonial exports was about 6 per cent higher than in 1955 and the value of imports rose by 9 per cent, the general pattern of Colonial trade showing little change.

Two new irrigation schemes have been inaugurated in Tanganyika, and progress is being made on three major irrigation projects in Kenya and in the exploitation of the limited water resources of Cyprus, while effect has been given to a scheme to establish an agricultural tractor and implement testing unit in

East Africa. Planning to ensure that the most suitable use is made of land is receiving much attention, and in the Gold Coast the swollen shoot campaign continued vigorously. Up to August 1956 more than 14 million acres of land, including 4 million acres of cocoa, had been extensively surveyed in this campaign, and spraying by farmers against capsid made good progress. Spraying against black pod in Nigeria is being intensified, and the acreage lost through cutting out in the campaign there against swollen shoot has been more than made good by new planting. A campaign in Cyprus against the Mediterranean fruit-fly is estimated to have resulted in savings of more than £250,000 in citrus fruit.

Good progress was again made in the execution of development and welfare schemes, expenditure on which rose to just over £17 million, with a further increase of about £26 million in the value of schemes approved during the year. Most Colonial governments have now drawn up plans for the current quinquennium, and it appears that Colonial governments and other public bodies plan to spend £150 million a year on development over the next few years, of which it is hoped to raise £30 million annually from external loans; about £15 million a year from Colonial Development and Welfare funds; and £15–20 million a year from local loans. The continued slump in world prices for cocoa was reflected in a further decline in Gold Coast Government revenues, resulting in curtailed funds for development and a call for economies in day-to-day expenditure, and in East Africa there was a marked fall in revenue from import duties; elsewhere there were no significant changes in the trends of revenue and expenditure. Encouraging increases continued in the volume of air traffic within, to and from the territories, and as a result of the resolution on the need for research in tropical meteorology passed by the 1955 Conference of Commonwealth Meteorologists, arrangements were made for a survey of the research requirements for tropical meteorology, by Dr. A. E. Forsdyke, of the British Meteorological Office.

Of the 4,858 students in the three universities and four university colleges of the Colonial territories, 1,574 were in the University of Malaya, 941 in the University of Hong Kong, 625 at Makerere College and 609 at University College, Ibadan. While these institutions continued to rely mainly on the United Kingdom for new staff, increasing numbers of local candidates were becoming qualified for teaching and administrative posts, and seven promising young Colonial graduates went to universities in the United Kingdom to fit themselves for teaching posts in their own colleges and universities. The Royal Technical College of East Africa, which opened in April, had 250 students for its first full session in October, the Kumasi College of Technology had 607 students and the Nigerian College of Arts, Science and Technology 549.

The emphasis placed on preventive medicine in recent years is reflected in a more stable balance in health programmes, with the community and social approach absorbing a fair share of departmental resources. The pattern of morbidity is veering away from the preponderance of tropical endemic disease to something more akin to disease-incidence ratios in temperate climates and, with the exception of malaria in hyperendemic areas, most of the parasitic diseases are coming under firmer control, tuberculosis now causing most general anxiety. Mass campaigns against yaws have met with notable success; but although 142 doctors were appointed to Medical Departments in 1956 through the Colonial Office, there were 135 vacancies outstanding at the end of the year. There were no widespread epidemics of the major acute communicable diseases, and in several non-tropical territories there are signs that tuberculosis is being successfully controlled. Recruitment of qualified nurses from the United Kingdom was maintained steadily throughout the year, but vacancies were only decreased from 165 to 102, and the acute shortage of nursing and midwifery tutors is causing anxiety. The training of nurses is still being given the highest priority in all territories. In June the Rockefeller Foundation made a grant of £17,000 to the London School of Hygiene and Tropical Medicine for research into the protein value of tropical dietaries and supplementary foodstuffs.

Of the 12,622 Colonial students in the United Kingdom and Irish Republic, 3,170 were scholarship holders and 3,365 were at universities; 1,295 were studying engineering; 1,075, medicine; 357, science; 308, economics; 117, agriculture; and 112, dentistry. Technical assistance projects in the Colonial territories under the United Nations Expanded Programme of Technical Assistance are estimated to cost 1,271,000 United States dollars in 1957, compared with 1,079,000 dollars in 1956. The report notes that the British teams participating in the international campaign against the desert locust in the Arabian peninsula were requested by the Government of Saudi Arabia to leave the country, and all personnel and equipment have been withdrawn.

UNIVERSITY GRANTS COMMITTEE

RETURNS FOR 1955–56

THE annual returns from universities and university colleges in receipt of Treasury grants for the academic year 1955–56, published by the University Grants Committee*, records an increase of 3,489 in the number of full-time students, which now stands at 85,194, compared with 81,705 in 1954–55, 80,602 in 1953–54 and 81,474 in 1952–53, and it is expected that the number in 1956–57 will show a further and greater increase as the number of full-time students in the autumn term of 1956 was 4,623 greater than in the autumn term of 1955. In the English universities, full-time men students increased by 1,997 and women by 714; for Wales, the corresponding figures were 71 and 61; and for Scotland, 400 and 246. There were 5,536 full-time and 2,068 part-time students from overseas within the British Commonwealth, and 3,750 full-time and 1,756 part-time students from foreign countries; for 1954–55 the corresponding figures were 4,987 and 2,010 for the Commonwealth and 3,617 and 1,594 for foreign countries. Distribution of full-time students among the faculties showed no significant change, an increase from 17,327 to 18,133 in students of pure science representing from 21·2 to 21·3 per cent of all students, and an increase from 10,586 to 11,379 in students of technology, representing 12·9 to 13·3 per cent of the total numbers. Full-time advanced students of pure science numbered 3,399 (34·6 per cent); of technology, 1,538 (15·6 per cent); of medicine and dentistry, 1,015 (10·3 per cent); and of agriculture, 322 (3·3 per cent); 2,832 students were working for the teacher's diploma. Of the full-time students, 67,850 were reading for a first degree, 4,021 for a first diploma, and 12,668 were engaged in research or other advanced work, the corresponding figures for 1954–55 being 64,778, 4,099 and 12,212.

---

* University Grants Committee. Returns from Universities and University Colleges in receipt of Treasury Grant, Academic Year 1955–1956. Pp. 60. (Cmnd. 211.) (London: H.M. Stationery Office, 1957.) 3s. 6d. net.

The proportion of assisted students was 74·9 per cent, compared with 72·9 per cent in 1954–55 and 71·9 per cent in 1953–54; for England as a whole this proportion increased from 74·9 to 76·8 per cent; for Scotland it increased from 59·5 to 62·2 per cent; and for Wales increased from 86·6 to 88·5 per cent. For the English universities and university colleges, excluding Oxford, Cambridge and London, 83 per cent were assisted students. The dependence on parliamentary grants was unchanged, the £26,986,519 received in 1955–56 again representing 70·4 per cent of the total income, that from fees increasing from 10·7 to 11·2 per cent, and payments for research from 5·5 to 6·0 per cent. Endowments represented 4·0 per cent, grants from local authorities 2·9 per cent and donations and subscriptions 1·0 per cent; for 1954–55 these figures were 4·1, 3·2 and 1·1 per cent, respectively. The ratio of staff to students continued to improve, the full-time teaching staff now numbering 10,202, compared with 9,810 in 1954–55.

Of the full-time students, 65,779 were in England (15,474 at Oxford and Cambridge, 19,029 at London), 4,626 in Wales and 14,789 in Scotland. Except for King's College, Durham, where the position was unchanged, the increase in students was distributed over all the universities and university colleges, approaching 10 per cent at Nottingham and Southampton. The proportion of full-time students living in colleges and halls of residence decreased to 27·5 per cent, although the total (23,415) was higher. Of those in residence, 8,110 were at Oxford and Cambridge, 12,186 at other English institutions, 1,268 in Wales and 1,851 in Scotland. The proportion of men in residence was 23·3 per cent and of women 40·1 per cent; whereas 38,072 students (44·7 per cent) were in lodgings and 23,707 (27·8 per cent) at home, compared with 42·8 and 29·3 per cent, respectively, during the previous year. Of the 23,990 students admitted for the first time in 1955–56 (an increase of 6·8 per cent on the previous year), 22,414 were reading for a first degree and 1,576 for a first diploma; of those reading for a first degree, 1,572 were less than eighteen years of age and 12,317 were nineteen or more. Of the full-time students, 37,897 out of 49,790 men and 12,534 out of 15,989 women in England were receiving assistance by way of scholarships, exhibitions or other awards from public or private funds; for Wales, the corresponding figures are 2,866 out of 3,528 men and 1,228 out of 1,368 women; and for Scotland, 6,784 out of 10,715 men and 2,421 out of 4,074 women. Of the 63,763 full-time men students, 36 per cent were in arts, 22·2 per cent in pure science, 16·3 per cent in medicine and 17·6 per cent in technology; for the 21,431 women students, the corresponding percentages are 64·0, 18·4, 13·8 and 0·7, respectively. Medicine and dentistry claimed 51·1 per cent of the part-time advanced students, arts 35·1 per cent, pure science 9·5 per cent, and technology 3·4 per cent, compared with 52·2, 34·9, 9·2 and 2·7 per cent, respectively, during 1954–55.

The recurrent income of the universities and university colleges of Great Britain increased by £2,716,573 to £38,316,651, and in addition to the recurrent grant of £26,986,519 included in this total, the universities received from the Treasury in 1955–56 non-recurrent grants totalling £7,084,366 in respect of capital expenditure. Of the recurrent expenditure of £38,038,270, an increase of 9·3 per cent on 1954–55, 7·0 per cent was spent on administration, 69·1 per cent on departmental maintenance, 12·3 on maintenance of premises, miscellaneous expenditure amounting to 10·5 per cent. The largest increases were in departmental wages (technicians and laboratory assistants) amounting to 14·6 per cent, and in repairs and maintenance of buildings, at 14·7 per cent. Expenditure on libraries (excluding general maintenance of such buildings) increased from £1,352,244 to £1,468,512. Statistics for the expenditure on the libraries of individual universities and university colleges included in the tables of comparative statistics again show how far such provision is from being adequate to meet existing needs, quite apart from coping with the expansion now beginning.

POLAROGRAPHIC WAVE ANALYSIS

By Dr. D. C. MUNRO

Royal College of Science and Technology, Glasgow

A POLAROGRAM—the plot of current against potential for a cell consisting of a reference anode and dropping mercury cathode—is most frequently constructed for determination of the diffusion current and hence of the concentration of some molecular or ionic species in the solution surrounding the dropping electrode. The half-wave potential for the reduction wave may also serve to characterize the reducible species. Less commonly, the shape of the wave has been used for determining the number of electrons involved in the reduction process taking place at the dropping electrode. A method is now described for determination of the electron number of the electrode reaction by direct measurement of the wave slope, and without the laborious graphing procedure used hitherto.

When reactions at the electrode surface are reversible, the shape of a polarographic reduction wave is described by the equation put forward by Heyrovsky and Ilkovic[1]

$$E = E_{1/2} - \frac{RT}{nF} \ln \frac{I}{I_d - I}$$

($E_{1/2}$ represents the half-wave potential in volts, I is the current at any point on the wave, and I_d is the final diffusion current.) Such waves have been analysed by plotting $\log I/(I_d - I)$ against E for points on the wave, and the number of electrons is

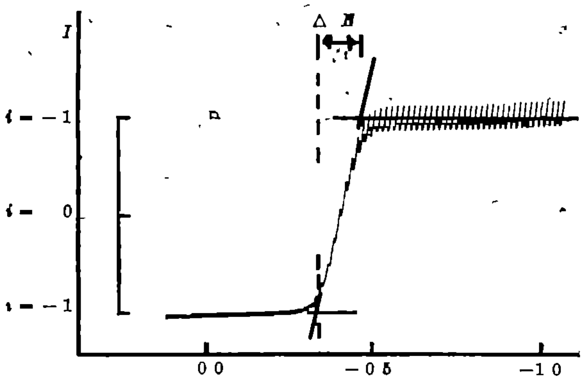

Fig. 1. Polarogram from a 4 × 10⁻⁴ *M* solution of thallous ion in molar tartaric acid. Construction lines show the three tangents and the significance of the potential increment (Δ*E*). The scale shows the current parameter *i*

determined from the slope of the line so obtained. The accuracy of this measurement is restricted by such factors as drop oscillations, differences in diffusion coefficients of reduced and oxidized species, and slow rates of reaction at the electrode surface.

For the greater part of the current increase, a normal polarographic wave approximates closely to the tangent at the half-wave point; and values of E and I for the graphing procedure are mainly taken from this portion of the wave, which is nearly linear. The equation of this tangent is most readily found in terms of a current parameter i, which is the difference between the current at any point and that at the half-wave point, expressed as a fraction of half the final diffusion current.

$$i = \frac{I - \frac{1}{2}I_d}{\frac{1}{2}I_d}, \text{ so that } \frac{I}{I_d - I} = \frac{1 + i}{1 - i}$$

At the commencement of a wave $i = -1$; at the half-wave point $i = 0$; and on completion of the wave $i = +1$. In the equation due to Heyrovsky and Ilkovic, the logarithmic terms may be expanded.

$$\ln \frac{1 + i}{1 - i} = 2\left(i + \frac{i^3}{3} + \frac{i^5}{5} + \frac{i^7}{7} + \ldots\right)$$

At the half-wave point, where $i = 0$, the tangent to the wave is described by the equation: $E = E_{1/2} - 2iRT/nF$. From the commencement of the wave ($I = 0$, $i = -1$) to the completion of the current increase ($I = I_d$, $i = +1$), the potential increment (ΔE) described by this tangent is $-4RT/nF$ volts; at 18° C., $\Delta E = -0{\cdot}1003/n$ volts. Thus the electron number of the reduction process is inversely proportional to this potential increment.

Fig. 1 shows a polarogram obtained from a solution of thallous ion, 4×10^{-4} *M* in molar tartaric acid. Construction lines illustrate the significance of ΔE, and the current parameter i.

The most satisfactory method for measurement of electron number is to compare the potential increment over a wave with that measured similarly for a reduction of known electron number, for example, that of thallous solutions. This procedure tends to compensate for errors in the drawing of the half-wave tangent.

Ion	ΔE (volts)	$\Delta E_{Tl}/\Delta E$
Tl^+	0·100	1 0
Pb^{2+}	0 056	1·8
Bi^{3+}	0·043	2 3

The validity of this procedure is indicated by the tabulated results, which were obtained from measurements on solutions, in molar tartaric acid, of Tl^+, Pb^{2+} and Bi^{3+}, each approximately 4×10^{-4} *M*.

ELECTRICAL DETERMINATION OF COLD HARDINESS IN *TRIFOLIUM REPENS* L. AND *MEDICAGO SATIVA* L.

By C. G. GREENHAM and H. DADAY

Commonwealth Scientific and Industrial Research Organization, Division of Plant Industry, Canberra

THE determination of cold hardiness, or conversely cold injury, is of considerable interest to plant breeders. The aim of our investigation has been to develop a rapid technique which can be used for establishing differences in cold hardiness between strains and between individual plants, particularly of certain forage legumes.

By cold hardiness we understand the ability of a plant or strain to withstand temperatures below freezing point with minimum subsequent injury. In spite of the work that has been done on the subject, no physiological test is currently in use for determining differences in cold hardiness between plants of the same variety or strain. The test devised by Dexter *et al.*[1] appears to be useful only for determining differences between strains. At present, survival after freezing is used as the criterion of hardiness in breeding programmes[2,3]. We use the term 'cold hardiness' rather than 'cold resistance' so that we can use the term resistance to mean electric resistance.

The subject of cold hardiness was reviewed by Levitt[4], who points out: (1) there is more than one kind of cold injury; (2) cold hardiness depends on the season; (3) there are several independent Mendelian factors responsible for cold hardiness; (4) hardy plants often possess relatively small cells; and (5) the factors of hardiness and small cell size can be separated by breeding. These facts have been kept in mind for the following investigation. In particular, we have been concerned with developing a method for measuring total injury resulting from a suitable cold treatment, rather than with measuring one or more factors responsible for cold hardiness.

Work on the determination of injury caused by poisons[5] suggested that the same test should be satisfactory for determining frost injury. The tissue under test is impaled on two needle tips (for example, 1½ mm. long and 5 mm. apart), and the electric resistance of the tissue is then measured at 1 kc./s. (R_{LF}) and at 1 Mc./s. (R_{HF}). The electrical resistance index $R_{LF}/R_{HL} \times 100$ is taken as the criterion for injury; as was shown in the course of the present experiments, the magnitude of this index decreases with increasing period of freezing or with increasing severity of freezing, becoming approximately 100 at death. The

Table 1. MEAN RESISTANCE INDEX VALUES FOR ECOTYPES OF *T repens*, WITH AND WITHOUT COLD TREATMENT

Population	Character	Exp. 1 (treated)	Exp. 2 (treated)	Exp. 3 (treated)	Exp. 4 (untreated)
Mediterranean	Cold susceptible	130†	240†	300†	730*
N. European	Cold hardy	630	690	790	800

Above values are means for 6–8 plants. The variation in mean values from experiment to experiment is attributable to variations in the rate of cooling of the refrigerator

* Significantly less than value vertically below it ($p < 0.05$)
† " " " " ($p < 0.001$)

arithmetical factor of 100 is included in the index for convenience.

Luyet[4] showed that in sliced healthy tissues, R_{LF} was considerably greater than R_{HF}, and that R_{LF} decreased with increasing injury, until at death it had approximately the same value as R_{HF}. However, he did not suggest the ratio of R_{LF}/R_{HF} as a criterion of vitality, or conversely of injury. The rationale behind this ratio as the criterion is that in healthy cells the impedance of the plasmalemma is mainly responsible for the high values of R_{LF}, but has essentially no influence on the magnitude of R_{HF}. With increasing injury the impedance of the plasmalemma falls and becomes negligible, affecting the magnitude of R_{LF} but not of R_{HF}. Advantages of using the ratio R_{LF}/R_{HF} in the above index are: (1) variations in R_{LF} are found to be at least partially compensated for in the same plant sample by corresponding variations in R_{HF}; (2) the magnitude of the ratio or index is essentially independent of cell size and therefore of the number of cells between the probe tips.

Distinction between ecotypes or strains. The material for test was selected from non-winter-hardy and winter-hardy ecotypes or strains of *T. repens* and *M. sativa*. The plants were grown under field conditions at Canberra, and measured during winter. They were removed from the field, the roots were cut off 4 in. below, and the stem 2–3 in. above, the plant crowns. Plant material thus prepared was given a pretreatment of 2 hr. at 2° C., was left for 8 hr. at − 8° C. in a refrigerator, then for one hour at − 2° C., and then kept in sealed vessels at 20° C. for 17 hr. before measurement with the apparatus described by Greenham[5]. Control material was kept at 20° throughout, without any freezing treatment. Four readings were made on each crown of *T. repens* and six to eight measurements on each crown of *M. sativa*. The mean value for each crown was used for statistical analyses. The measurements were made on the crowns as that material was the least variable.

Measurements were made on ecotypes of *T. repens* from extreme geographical regions of Europe. Table 1 shows that, for the treated plants, the mean for a Mediterranean population is significantly less than that for a north European population ($p < 0.001$).

We interpret this as showing that the former populations were more injured than the latter. Moreover, Table 1 shows that a slight but significant difference in resistance index value can occur between ecotypes exposed to frost in the field during winter in Canberra. At this stage we cannot say if this difference is due to frost injury in the field.

The strains of *M. sativa* used were the Hunter River strain (Australian) and Ladak and Canadian creeping-rooted strains, the two latter obtained from the cold winter regions of North America. After treatment the mean resistance index value was 200 for the cold-susceptible Hunter River strain, and 470 and 480 for the cold-hardy Ladak and Canadian creeping-rooted strains, respectively. The difference between the cold-susceptible and cold-hardy strains is highly significant ($p < 0.001$), but the difference between Ladak and Canadian creeping strains is not significant. The mean resistance index value for the control plants (without any artificial cold treatment) did not indicate any significant difference (Hunter River 523, Canadian creeping-rooted 566). There were insufficient Ladak plants to be included in the test of controls.

We therefore conclude that the resistance index method can be used for the rapid discrimination of cold-susceptible and cold-hardy strains (two assistants can measure 120 plants in 8 hr.). A particular convenience of the test is that after measurement the crowns can be planted out to test for recovery.

A note may be added concerning the claim that the strains or ecotypes used are cold-susceptible or cold-hardy as has been indicated above. From the nature of their original climates, there is every reason to regard the north European populations of *T. repens* as considerably more cold-hardy than Mediterranean populations. Moreover, it is reasonable to expect a correlation between the cold-hardiness of the crowns and that of the stolons. In fact, the cold-treated stolons of the plants used for Table 1 were planted out after the test on the crowns. More than 50 per cent of the twenty stolons from the treated north European population recovered, whereas none of the twenty-two stolons from the treated Mediterranean population recovered. Other experiments have shown that there can be 80–100 per cent recovery from any untreated population (even with untreated plants, a few may not recover from being transplanted).

As regards *M. sativa*, the Hunter River strain was derived from the very cold-susceptible Provence strain[7], and has been continuously grown in the mild winter region of Australia. The cold-hardiness of the Ladak and Canadian creeping lucerne has been described by Heinrichs[8]. In addition, we have found by the Dexter test that the Hunter River lucerne is more injured by cold treatment than either of the two Canadian strains ($p < 0.001$) and that there was no significant difference between the Canadian strains.

Effect of increasing cold treatment and distinction between individual plants. The material (*T. repens*) was dug from five different localities at Mt. Kosciusko, all within a radius of a few miles and as close as possible to snow. The material was brought to Canberra in paper bags in a metal container. Material from each locality was divided into five different groups, four of which were given the same pretreatment as before and then subjected to − 6° C. for 1, 2, 4 and 8 hr. (the 0 hr. groups were kept in sealed jars at 20° C. and had no pre-treatment). After treatment, measurements as described previously were made on the stolons and also on the crowns when present and large enough (the plants varied considerably in size). After measurement, the stolons or stolons with crowns attached were planted out and checked for recovery five weeks later.

Table 2. CORRELATION BETWEEN RESISTANCE INDEX AND RECOVERY AFTER VARIOUS COLD TREATMENTS APPLIED TO STOLONS OF *T. repens* (APPROXIMATELY 50 PLANTS PER LOCALITY)

Treatment (hr at -6° C.)	Locality 1		Locality 2		Locality 3		Locality 4		Locality 5	
	Mean index	Survival (per cent)	Mean index	Survival (per cent)	Mean index	Survival (per cent)	Mean index	Survival (per cent)	Mean index	Survival (per cent)
0	860	80	740	90	890	100	630	90	730	90
1	730	44	740	75	750	75	690	56	720	67
2	420	40	640	30	440	25	330	11	460	40
4	390	0	230	22	250	11	200	0	250	0
8	240	0	310	10	170	0	180	0	140	0

Treatment effect highly significant ($p < 0\cdot001$). Location effect significant ($p < 0\cdot05$)

An analysis of variance (Table 2) was carried out on the stolon resistance index readings for the five populations subjected to various cold treatments. The treatment effect is highly significant ($p < 0\cdot001$) and the location effect is also significant ($p < 0\cdot05$). These results show that increasing the length of cold treatment causes greater injury to the plants and that there is a progressive and corresponding decrease in resistance index values. Covariance analyses of the angular transformation of the percentage survival on the resistance index indicate that the relationship between survival and index is highly significant ($p < 0\cdot001$). There is no significant residual variation between places in percentage survival when the differences in resistance index are taken into account. This suggests that the factors responsible for the differences in resistance index between locations are similar to, or identical with, the effects of exposure to cold in the experimental arrangement. The results for the crowns were fragmentary. The regression coefficient of mortality on resistance index, while not significant, was more than twice that for the stolons.

The analyses so far considered are the effects of treatment and localities on resistance indexes and mortality for populations of plants. Of greater practical interest is the possibility of predicting recovery from cold injury for plants which have been subjected to the same test conditions. For this purpose the results were regrouped, within treatments, into classes according to the resistance index. Locations were ignored because of the finding of the covariance analyses. For each class the percentage survival was calculated and a regression of transformed percentage survival on resistance index determined. A limited number of plant crowns was included in the recovery test. Twenty-five plant crowns received the 8-hr. treatments and they exhibited resistance index readings in the range 115–245; all failed to recover. Nine crowns were included in the control group, with resistance index readings in the range 382–535; all but one recovered within a few days. Within the other three treatments, there were sufficient crowns or sufficient range in recovery for statistical analyses to be carried out on only the 2-hr. treatment (with total of 17 crowns).

Table 3. REGRESSION COEFFICIENTS OF STOLONS AND CROWN ANALYSES OF *T. repens*

Treatment	Stolons	Crowns
0	7·2	—
1	4·3	—
2	8·1	21·7*
4	—	—
8	—	

* $p < 0\cdot05$

Only the regression of mortality on resistance ratio for crowns with 2-hr. exposure to cold was significant, but the coefficients are constantly positive.

Despite the limited amount of material and the variability in its size, there is good indication that the magnitude of resistance index of a crown after cold injury gives a measure of the probability of recovery. (The resistance index method has also shown promise for determining the injury caused by drought—Greenham and Morley, unpublished.) Other experiments also suggest that it is preferable to make readings on the crowns rather than on the more variable stolons. Further investigations are planned.

We are indebted to Mr. G. A. McIntyre and Mr. M. L. Dudzinski for the statistical analyses.

THE VITAMIN-SPARING ACTION OF SORBITOL

By T. B. MORGAN and PROF. JOHN YUDKIN
Department of Nutrition, Queen Elizabeth College, University of London

IN the complete absence of dietary carbohydrate, rats are able to survive without thiamine for many months[1]. As little as 5 or 10 per cent of glucose in the diets leads to polyneuritis and death. It seems that signs of thiamine deficiency are due to the products of perverted carbohydrate metabolism[1,2], and we might look upon dietary carbohydrate as a toxic substance, the antidote to which is thiamine.

It occurred to us that these observations might allow us to determine whether a given dietary component was or was not metabolized as ordinary carbohydrate. In particular, we tried to resolve the uncertainty concerning the metabolism of sorbitol. It turned out that we were not able to do this, for our results revealed a remarkable effect of sorbitol on intestinal synthesis of B vitamins.

When we gave sorbitol to rats at levels of up to 20 per cent of the carbohydrate-free diet without thiamine, we found that they survived for 30 weeks and were still gaining weight. The same amounts of glucose led to loss of weight, polyneuritis and death in 5–10 weeks. Moreover, the animals receiving sorbitol grew much better and were in a healthier condition than those receiving the carbohydrate-free diet (Table 1).

Table 1. EFFECT OF SORBITOL ON GROWTH AND SURVIVAL OF RATS ON THIAMINE-FREE DIETS

The experiment was begun with male, piebald rats, aged 47 days, four in each group. Diets contained 5 per cent mineral salts and were supplemented with all vitamins except thiamine. The carbohydrate-free diets contained casein 80 per cent, arachis oil 15 per cent; in the other diets, 5 per cent or 10 per cent glucose or sorbitol replaced the same amount of casein

Diet	Initial weight (gm.)	Survival (days)	Weight at death or at 80 days (gm.)
Carbohydrate-free	138	> 80	138
5 per cent glucose	132	57	81
5 per cent sorbitol	135	> 80	202
Carbohydrate-free	133	> 80	132
10 per cent glucose	130	48	85
10 per cent sorbitol	132	> 80	220

We now added sorbitol to thiamine-free diets containing sugar. When added to diets containing up to 40 per cent glucose, 10 per cent sorbitol gave at least as good growth as when added to carbohydrate-free diets.

These effects might have been due to thiamine as a contaminant of the sorbitol. This was unlikely, since sorbitol is made from glucose. Nevertheless, we have assayed it for thiamine by the thiochrome method and could find none.

A second possibility was that the sorbitol produces a change in the intestinal flora of the rats, so that thiamine is synthesized and is available to the host. We believe that this is what in fact occurs. The evidence is: (1) Sorbitol has a profound effect upon intestinal function. Rats put on to a diet containing 30 per cent or more of sorbitol develop severe diarrhœa and may die. With 20 per cent, a transitory diarrhœa develops, after which the amount of sorbitol may slowly be increased to 50 per cent with no further ill-effects. (2) Rats fed sorbitol for a few weeks develop greatly enlarged cæca. With 30 per cent dietary sorbitol, the weights of the cæca are three times as great as those of the control animals (Table 2). The contents are equally increased, and are much more fluid. There is less increase in the weight of the large intestine and small intestine, and no change in the weight of the stomach. (3) The tissues of rats surviving on thiamine-free diets with sorbitol contain more thiamine than those of rats moribund on thiamine-free diets with glucose. Thus, thiamine is being made available to the tissues, though not from the diet.

We are now examining the intestinal flora to see what differences are induced by sorbitol. We are also investigating other substances which, like sorbitol, may render animals independent of dietary thiamine. Finally, we are examining the possibility that nutrients other than thiamine may be produced by the administration of sorbitol.

We have so far begun an investigation to see whether sorbitol can make animals independent of dietary sources of other vitamins of the B group. Since it will take some time to investigate these singly, as we have done with thiamine, we began with one or two preliminary experiments in which most or all of the B vitamins were omitted from the diet. By this means, we hoped that the condition of the animals would give us a clue as to which of the vitamins were not being provided by the action of the sorbitol on the alimentary microflora. In such an experiment, one group of animals was given 20 per cent sorbitol with only choline and inositol of the B group. That is, they were not given thiamine, riboflavine, nicotinic acid, pyridoxine, pantothenic acid, *p*-aminobenzoic acid, biotin, folic acid or vitamin B_{12}. One set of control animals was also given only choline and inositol, but with no sorbitol. As we expected, these died in 4–5 weeks from thiamine deficiency. Since we know that sorbitol renders animals independent of dietary thiamine, we gave a second set of control animals choline and inositol and thiamine, with no sorbitol. These survived for more than three months but did not gain weight and were in very poor condition. The experimental animals receiving the 20 per cent sorbitol, however, with only choline and inositol of the B group of vitamins, showed the usual initial small loss in weight but then began to gain weight and continued to do so over the same period (Fig. 1).

Table 2. EFFECT OF SORBITOL ON WEIGHT OF ALIMENTARY CANAL. FIVE ANIMALS IN EACH GROUP

Organ	Wet weight (gm.)		Ratio B/A
	Diet without sorbitol A	Diet with sorbitol B	
Small intestine	3·75	5·06	1·3
Cæcum	0·43	1·29	3·0
Cæcum with contents	1·95	7·32	3·7
Large intestine	0·69	1·23	1·8
Average weight of animals	239	247	

This surprising result led us to put some animals on a diet with sorbitol but with none of the vitamins of the B group. They have also continued to grow well for more than three months (Fig. 2).

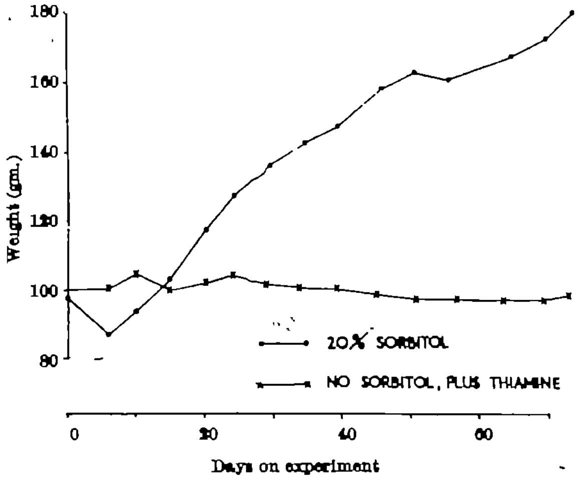

Fig. 1. Effect of sorbitol on growth of rats on vitamin B-deficient diets

Exp. 1. Four male piebald rats in each group. Both diets contained 5 per cent salts, 15 per cent arachis oil, 20 per cent casein. In addition, the control rats had 60 per cent sucrose, the experimental rats 40 per cent sucrose and 20 per cent sorbitol. Both diets also contained vitamins A, D, E and K, and choline and inositol of the vitamin B group. The control animals had thiamine in addition

We have changed over the diets of some of the animals receiving or not receiving sorbitol. The change to sorbitol resulted in a prompt increase in weight, as if the change in microflora giving the B vitamins occurred rapidly (Fig. 3). The change from a sorbitol-containing diet to one without sorbitol, but with vitamin B_1, produced no effect for a few days, and then led to a fall in weight (Figs. 3 and 4). This does not necessarily mean that the microbial change is less rapid than that occurring when the dietary change is in the opposite direction. It could be explained by the time taken for the vitamin concentration in the tissues to fall to an inadequate level.

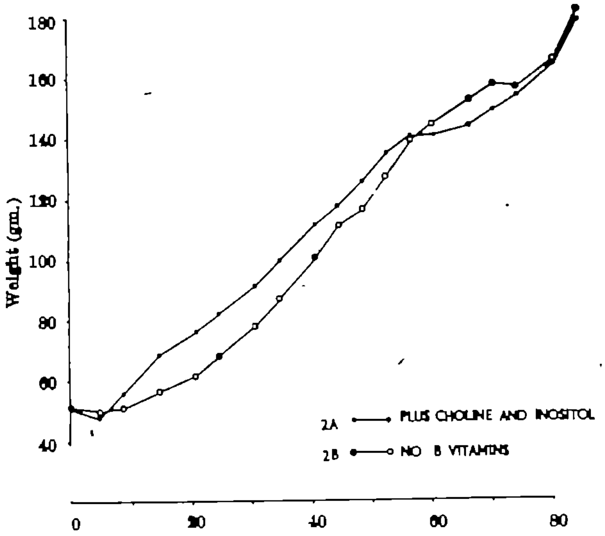

Fig. 2. Effect of sorbitol on growth of rats on vitamin B-deficient diets

Exp. 2. Three male piebald rats in each group. *A*, diet as experimental diet in Exp. 1; *B*, diet as *A*, but with no choline or inositol

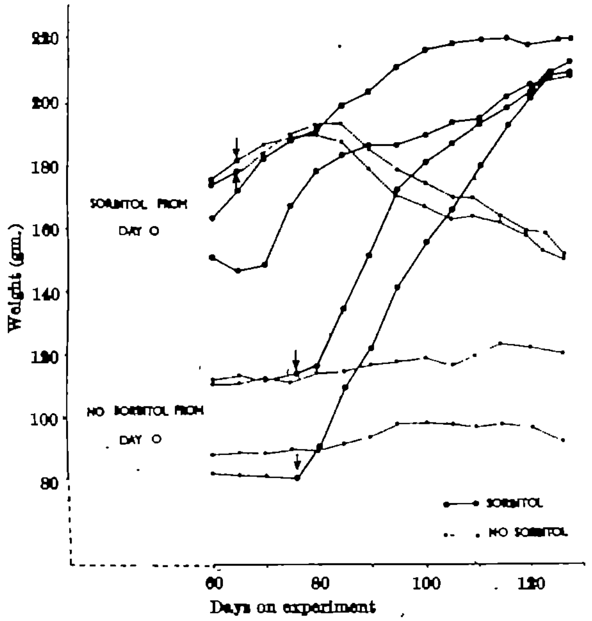

Fig. 3. Effect of change of diet

Each curve represents the growth of one animal from Exp. 1 (Fig. 1). At the indicated times, the diet of two rats in each group was changed to that of the other group. The diet of the two remaining rats in each group was unchanged

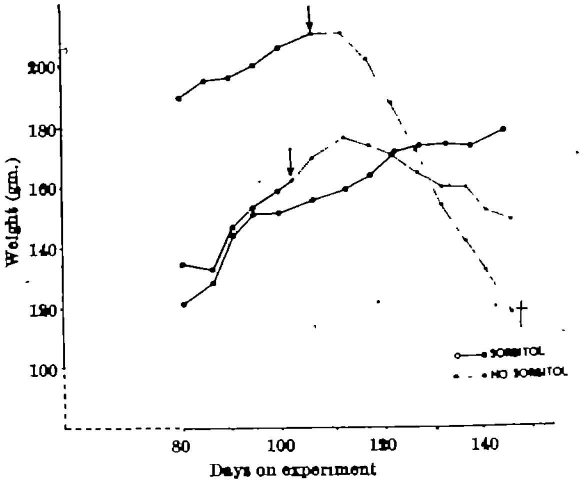

Fig. 4A

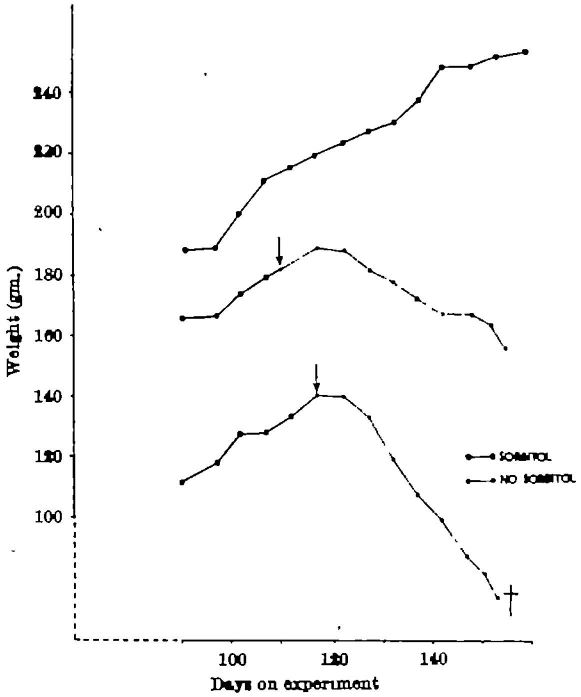

Fig. 4B

Fig. 4. Effect of change of diet

Each curve represents the growth of one animal from Exp. 2 (Fig. 2). At the indicated times, the sorbitol-containing diet of two of the three rats in each group was changed to the sorbitol-free diet with thiamine. *A*, diet with choline and inositol; *B*, diet with no choline or inositol

Thus, the administration of sorbitol appears to make an animal independent of dietary sources, not only of thiamine, but also of the other vitamins of the B group. We know of no similar report of a substance which can lead to intestinal synthesis of much of, if not all, the required amounts of all the vitamins of the B group. Our programme of further work includes a study of the effect of sorbitol on intestinal synthesis[1,2] of vitamins in man.

Evidence for the Formation of a Labile Phospholipoprotein during the Clotting of Platelet-rich Plasma

WHEN plasma containing platelets clots at 37° C., the adenosine triphosphate in the platelets rapidly breaks down; little or none of it appears in the serum[1]. It has now been found that during clotting an increased amount of phosphate becomes bound to protein. The phosphate seems to come partly from platelet adenosine triphosphate and partly from phospholipid. One of the experiments which demonstrated this was as follows.

All glassware with which blood or plasma came into contact before clotting was induced was treated with silicone. 80 ml. of human blood was obtained from an arm vein and mixed with 1·6 ml. of 19 per cent (w/v) sodium citrate. The blood was centrifuged at 500*g* for 20 min. at 1° C. 30 ml. of plasma was obtained, containing 4·2 × 10^8 platelets/ml.

The plasma was dialysed for 24 hr. at 2–4° C. against 5 litres of Krebs's bicarbonate solution which was modified so as to contain no phosphate. The solution contained 20 ml. of 19 per cent sodium citrate per litre and it was gassed with a mixture of 95 per cent oxygen and 5 per cent carbon dioxide. 15 ml. plasma was centrifuged at 25,000*g* for 20 min. at 1° C. The sedimented platelets were extracted as described below.

Two series of glass tubes were prepared. These tubes were not treated with silicone. The tubes of the first series contained 2·5 ml. of platelet-free plasma and those of the second series 2·5 ml. of platelet-rich plasma. The tubes were incubated in a water-bath at 37° C. 0·06 ml. of *M* calcium chloride was mixed with the plasma in each tube. Clotting began after 5 min. in the platelet-rich plasma and after 10 min. in the platelet-free plasma. 0, 4, 8, 16 and 32 min. after adding the calcium chloride, 1 ml. of ice-cold 40 per cent trichloracetic acid was added to one tube of each series. The tubes were cooled in ice-water and the contents were dispersed.

The tubes were centrifuged at 3,000*g* for 10 min. at 1° C. The supernatant solutions were retained and each precipitate was extracted with 10 per cent (w/v) trichloracetic acid and then twice with water. The extracts were added to the first supernatant. The solutions were analysed for total phosphate, inorganic phosphate and organic phosphate which was hydrolysed in 10 min. in *N* hydrochloric acid at 100° C. ('10 min. phosphate'). The '10 min. phosphate' extracted from dialysed platelet-rich plasma by trichloracetic acid is almost wholly derived from adenosine triphosphate in the platelets (unpublished results). Phosphate was determined by the method of Berenblum and Chain[2].

The precipitates were dried in a vacuum over phosphorus pentoxide. They were extracted twice with a mixture containing 2 parts of chloroform and 1 part of methanol. The extracts were washed by the method of Folch[3] and the extracts and washings were analysed for total phosphate. The residues were dried and resuspended in water. Samples of each suspension were analysed for total phosphate, and for nitrogen by the micro-Kjeldahl method. The results are shown in Fig. 1.

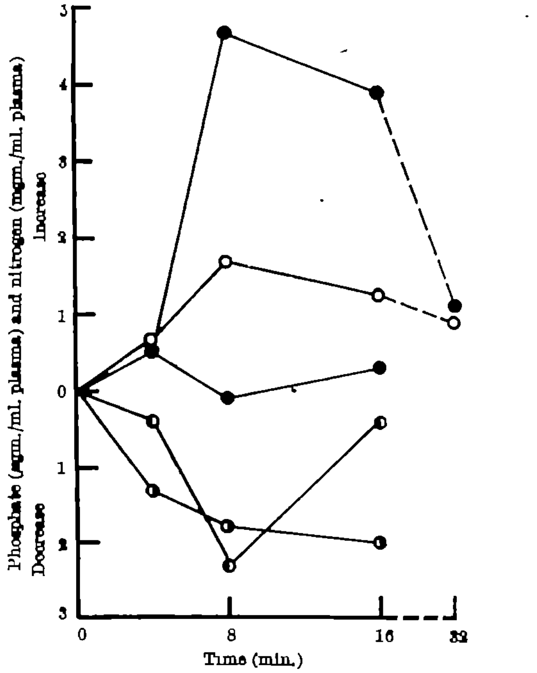

Fig. 1. Changes in the concentrations of phosphate and nitrogen during clotting of plasma. In plasma free of platelets: ◒, Phosphate in residue. In plasma containing platelets: ●, Phosphate, and ○, nitrogen, in residue; ◑, '10-min. phosphate'; ◐, phosphate extracted by chloroform plus methanol

When the plasma clotted in the presence of platelets, the phosphate which could not be extracted from the residue increased by 4·7 μgm./ml. plasma after 8 min. and then decreased. The nitrogen in the residue increased and decreased at the same time. These changes did not occur when plasma clotted in the absence of platelets.

As the phosphate in the residue increased, the '10 min. phosphate' decreased by 1·8 μgm./ml. plasma, and the phosphate extractable by chloroform plus methanol decreased by about 2·3 μgm./ml. plasma. The last figure is less accurate because the amount of phosphate in the lipid extract was large (89 μgm./ml. plasma) compared with the changes which occurred during clotting.

The residue left after extracting with trichloracetic acid, water and chloroform plus methanol is presumably almost entirely protein since plasma contains no nucleic acids and platelets contain only small amounts[4]. Therefore the results suggest that, when platelet-rich plasma clots, increased amounts of phosphate become bound to protein, and that the phosphate comes from phospholipid, and from adenosine triphosphate in the platelets. It seems that a phospholipoprotein is formed which is afterwards broken down.

The rate of formation and destruction of the phospholipoprotein observed in this experiment is very similar to the rate of formation and destruction of 'thromboplastin'. It is known that little 'thromboplastin' is formed unless fresh platelets are present[5]. The results suggest, therefore, that plasma 'thromboplastin' is a phospholipoprotein which is formed during clotting when platelets are present. The formation of the phospholipoprotein may involve adenosine triphosphate in the platelets.

This work will be reported more fully elsewhere.

Effect of Cerebral Lesions upon Œstrus in Ferrets

Numerous clinical and experimental observations that have been reported over the past fifty years have led to the concept that the hypothalamus is the seat of specific nervous centres which subserve a variety of visceral functions. Among these are supposed to be 'sexual centres' which control: (*a*) the release of luteinizing hormone[1]; (*b*) all the gonadotrophic functions of the pituitary[2]; (*c*) ovulation[3–5]; (*d*) patterns of sexual behaviour[6,7]; (*e*) the inhibition of follicle-stimulating hormone[8,9].

The location of some of these presumed centres varies with different authors, and the same hypothalamic nuclei have been endowed by different writers with the control of completely different visceral functions (see Zuckerman[10]).

The following observations refer to the suggestion that the anterior hypothalamus of the ferret contains a centre which inhibits the production of follicle-stimulating hormone during the anœstrum. This belief is based upon the observation of Donovan and v.d. Werff t. Bosch[8,9] that bilateral lesions made during the winter in this part of the hypothalamus result in the precocious appearance of œstrus.

Nucleus centralis medialis
Nucleus medialis dorsalis

Fig. 1. Bilateral lesions in the thalamus of a ferret. × 13

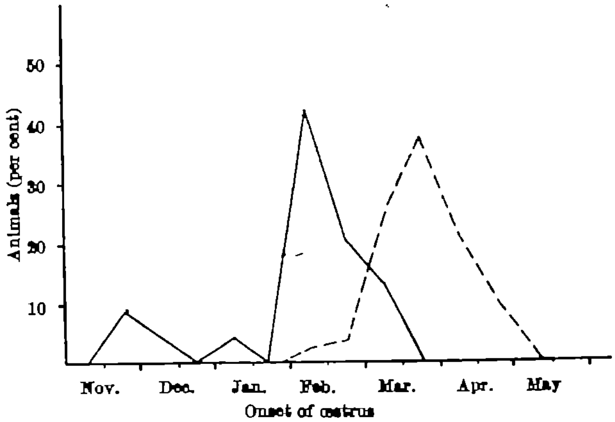

Fig. 2. Onset of œstrus in control (pecked line) and experimental (full line) animals

Bilateral electrolytic lesions were made with the help of a stereotaxic device either in the thalamus, the caudate nucleus or the fornix of fourteen mature female ferrets between September 20 and December 13, 1956 (see Fig. 1). A current of 50 m.amp./sec. was used, except in the case of three animals, when 30 m.amp./sec. were passed. A single pair of lesions was made in all cases except one, in which three were made. The lesions were between 1 and 2 mm. in diameter.

Control operations were made in ten animals, in which the electrode was inserted into the brain substance and withdrawn without a current having been passed.

Information about the normal time of onset of œstrus in intact animals was provided by the records of 145 ferrets kept in this laboratory over the preceding ten years (including 8 during the current season).

Fig. 2 shows that œstrus occurred much earlier in both sets of operated ferrets than in the unoperated animals. Its onset was accelerated in animals in which the electrode was inserted without a current being passed, as well as in animals in which a current was passed. In this respect there was no constant relation in the time of onset of œstrus between any individual ferret bearing lesions and the corresponding control-operated animal. Nor was the speed with which œstrus occurred correlated either with the date of operation or with the size, position or number of the lesions.

These results suggest that the acceleration of œstrus following operations on the brain provides no justification for assigning any specific sexual or reproductive function to any part of the brain of the ferret. In particular, they show that the fact that œstrus may be accelerated when lesions are made in the anterior hypothalamus provides no more basis for positing the existence of a sexual centre in that part of the brain than the present experiments do for the view that such a centre exists in the thalamus or caudate nucleus. The possibility that the acceleration of œstrus following intracranial operations may constitute a form of non-specific stress of the kind which leads to precocious puberty in the rat (for example, Mandl and Zuckerman[11,12]) is now being investigated.

Utilization of Carbohydrate Metabolites by Rumen Micro-organisms

HERSHBERGER *et al.*[1] have recently published observations concerning the *in vitro* study of the utilization of carbohydrates and carbohydrate metabolites by rumen micro-organisms. Using a basal salt medium with an inoculum of sheep rumen liquor and a 24-hr. incubation period, these workers determined, *inter alia*, the volatile fatty acid production from pyruvic acid and lactic acid and obtained the following results (Table 1).

In somewhat similar studies in this laboratory corresponding results were obtained which are shown in Table 2. In this work the general procedures, except for the determination of volatile fatty acids, were those of Barnett and Reid[2]. The basal salts medium was that described by Burroughs *et al.*[3]; substrates were added to a concentration of 7·7 mgm./ml.; anaerobic conditions were maintained by passing carbon dioxide through the incubation mixture at 39° for 72 hr.; the initial *p*H was 6·7 and seldom fell below 6·5 but was adjusted when necessary to the initial value twice every 24 hr. by the addition of *N* sodium carbonate; the rumen liquor used in this work was obtained from fresh slaughter-house rumens and maintained at 37° during transport to the laboratory, where it was strained through muslin before use; volatile fatty acids were determined on steam distillates from the artificial rumen by the technique of James and Martin[4].

From the above information the following observations may be made: (1) Acetic acid is produced in greater amount than propionic acid from pyruvate, whereas propionic acid is the chief acid derived from lactate—in our experiments the excess was very great. (2) Pyruvic acid and lactic acid differ also with respect to butyric acid production, but in each case the total amounts of C_2–C_5 volatile fatty acids produced are similar. (3) α-Ketoglutarate gives a low total production of volatile fatty acids, mainly acetic and propionic acids.

Table 1. PRODUCTION OF VOLATILE FATTY ACIDS OBTAINED BY THE INCUBATION OF PYRUVIC ACID AND LACTIC ACID, AS SOLE ADDED CARBON SUBSTRATES, FOR 24 HR. WITH A RUMEN LIQUOR/MINERAL SALT MEDIUM (REF. 1)

Substrate	m.moles acid/100 ml. 'rumen' contents			
	Acetic	Propionic	Butyric	Total
Salt medium + rumen liquor + pyruvate	6·76	0·90	1·08	8·74
Salt medium + rumen liquor + lactate	4·15	4·51	0·32	8·98

Table 2. PRODUCTION OF VOLATILE FATTY ACIDS OBTAINED BY THE INCUBATION OF PYRUVATE, LACTATE AND α-KETOGLUTARATE AS SOLE ADDED CARBON SUBSTRATE, FOR 72 HR. WITH A RUMEN LIQUOR/MINERAL SALT MEDIUM AT *p*H 6·7 AND 39° IN AN ATMOSPHERE OF CARBON DIOXIDE

Substrate	Proportional distribution of volatile fatty acids (per cent)						Total volatile fatty acids (mgm./100 ml. 'rumen' fluid)
	C_2	C_3	*iso*-C_4	*n*-C_4	*iso*-C_5	*n*-C_5	
Salt medium + rumen liquor + pyruvate	80·0	5·8	0	9·5	2·6	2·1	300
Salt medium + rumen liquor + lactate	20·3	51·8	0·8	21·1	1·6	4·4	280
Salt medium + rumen liquor + α-ketoglutarate	61·5	30·2	0	4·3	0	4·0	60

To explain the above observations, it may be recalled that in Propionibacteria it has been suggested that propionic acid is formed from succinic acid by decarboxylation[5]. There is evidence[6] that succinic acid may be produced from intermediates such as lactic acid or pyruvic acid in either of two ways: (*a*) by conversion of pyruvic into oxaloacetic acid and thence through malate and fumarate into succinate; (*b*) by condensation of acetate (derived from pyruvate) with oxaloacetate to yield citrate and hence through the steps of the tricarboxylic acid cycle to give succinate. A modification of the latter process might involve the recently described glyoxylic acid cycle (Kornberg and Krebs[7]), according to which the citrate will yield succinate and glyoxylic acid; the latter, by condensation with acetate, will yield malate and thence oxaloacetate to continue the cycle.

The characteristic feature of route (*a*) is that it involves the reduction of fumarate to succinate by the enzyme succinic acid dehydrogenase. This enzyme catalyses the interconversion of succinate and fumarate reversibly and is inhibited by malonate[8].

A preliminary experiment in the present work has indicated that production of propionic acid from lactate is very substantially reduced if malonate is present, and so it would appear that in our experiments route (*a*) is important in the production of propionic acid, a result in general agreement with those of Hershberger *et al.* (*loc. cit.*). This observation is supported by the fact that α-ketoglutarate gives little propionate, although the interpretation of the results is complicated by the possible low permeability of the cells to α-ketoglutarate.

It is to be observed that when lactate is used as substrate in these experiments as opposed to pyruvate, the conversion of lactate to pyruvate under the influence of lactic acid dehydrogenase involves the formation of reduced diphosphopyridine nucleotide and a supply of this is required for the reduction of oxaloacetate to malate and (indirectly) for the reduction of fumarate to succinate. Thus it is not surprising that in the anaerobic conditions of the experiment the ratio of propionate to acetate is greater with lactate than with pyruvate. It has been suggested by Fitz[9] and by von Freudenreich and Orla Jensen[10] that lactic acid (3 moles) may undergo dissimilation to propionic acid (2 moles) and acetic acid (1 mole). In the absence of a detailed mechanism, this reaction may be regarded as a summary of the overall process postulated here.

The acetate formed under the anaerobic conditions of our experiments is likely to be produced from pyruvate by hydrolytic fission into acetate and formate rather than by the oxidative decarboxylation characteristic of aerobic tissues.

These ideas are summarized in the following scheme:

Accumulation of a Stable Phosphorus Compound in Glycolysing Insect Muscle

In isolated metathoraxes of the cockroach *Periplaneta americana*, 85 per cent of the mass of which is formed by the thoracic muscles, changes in various fractions of acid-soluble phosphorus compounds were followed during exposure of the preparations to anoxia. It was found that in such conditions there is a rapid breakdown of the labile phosphorus compounds, namely, arginine phosphate and adenosine triphosphate[1]. At the same time, however, the level of inorganic phosphate did not increase significantly; on the contrary, in many cases it showed a tendency to decrease. As the total acid-soluble phosphorus did not change at all, these facts indicated an accumulation of some stable phosphorus compound during anaerobiosis: this compound was found to be stable even to prolonged acid hydrolysis (three hours in normal acid).

To obtain some information about the nature of this compound, the trichloroacetic acid extract of the muscles was subjected to fractionation by means of the salts of alkaline earth metals[2]. For this purpose six hemi-metathoraxes weighing about 0·6 gm. were combined, the symmetrical halves serving as control. The stable ester formed in anaerobiosis was found quantitatively in the barium soluble – alcohol insoluble fraction. Its phosphate could not be split off by heating in normal alkali hydroxide for three hours; it was, however, liberated readily by subsequent heating with periodic acid in normal sulphuric acid. Thus the compound accumulated during anaerobiosis is most probably glycerophosphoric acid. The amount of phosphate split off by periodic acid treatment and the calculated amount of glycerophosphate, expressed as glycerol, are given in Table 1.

Table 1. Stable Phosphate Ester in Cockroach Metathoraxes

Phosphorus split off by periodic acid treatment (mgm. per 100 gm.)			Glycerol equivalent to the increase in phosphorus (mgm. per 100 gm.)
Aerobic	After 40 min. anaerobiosis	Increase during anaerobiosis	
5	36	31	92
13	55	42	124
20	52	32	95
9	32·5	23·5	70

The formation of glycerophosphate in insect muscle during glycolysis is quite possible, as the activity of α-glycerophosphate dehydrogenase was found to be very high in this tissue[3]. In parallel experiments, during the same period of anaerobiosis, glycogen breakdown was found to be equivalent to 250 ± 33 mgm. per cent glucose in these preparations; thus glycerophosphate would constitute a considerable proportion of the breakdown products, which would explain low yields of lactic acid in glycolysing insect muscle[4]. As glycerophosphate would be most probably formed by triosephosphate dismutation, the occurrence of pyruvate among the products of insect glycolysis[5] would also be explained.

Isolation of 2-Aminoethanesulphinic Acid from a Mollusc

Paper chromatographic analyses of extracts from *Septifer* (*Mytilisepta*) *virgatus* (Wiegmann) by means of the iodine–azide reaction[1] showed the presence of an unusual sulphur compound, leading to its isolation. The isolate was identified as 2-aminoethanesulphinic acid. In 1951 Bergeret and Chatagner[2] observed paper chromatographically that this compound was formed from cysteinesulphinic acid by the action of liver acetone powder. Furthermore, in 1953, Awapara and Wingo[3] isolated ^{35}S-2-aminoethanesulphinic acid and ^{35}S-taurine from rat liver after injection of ^{35}S-cysteine. 2-Aminoethanesulphinic acid, however, has never been reported to be isolated directly from organisms under natural conditions without administration of the precursors such as cysteinesulphinic acid, cysteine or cystine. We have found that every tissue of this *Septifer* contains this compound in considerable quantity.

Shells of the *Septifer* were removed and the contents were ground in a mixer with water. The extract was deproteinized with ethanol, centrifuged, the precipitate separated from the supernatant liquid was washed with water, and the washings after deproteinization and centrifugation were mixed with the supernatant liquid obtained above. The mixed solution was passed through a column of 'Amberlite *IR*-120' in the acid form. After washing the column with water, the fraction containing the sulphinic acid was eluted with about 1 *N* ammonia. The elute was evaporated up to dryness under reduced pressure in an inert gas. The residue was then dissolved in a small amount of water. After removal of the insoluble part, the solution was passed through a column of 'Amberlite *IRC*-50' previously treated with hydrochloric acid. The resultant solution was again passed through a column of 'Amberlite *IR*-4*B*' previously treated with a sodium hydroxide solution. The latter two operations were repeated two to three times. By these procedures a considerable amount of impurity was removed. The fairly pure sulphinic acid fraction obtained thus was treated once more with about ten times as much as necessary of the acid form of 'Amberlite *IR*-120' to adsorb the required compound completely; the latter was found only in the first effluent portion by elution with about 0·01 *N* hydrochloric acid. When this portion was concentrated under reduced pressure and then allowed to stand out of contact with air in an icebox with the addition of ethanol, colourless crystals of the sulphinic acid appeared. Approximately 30 mgm. was obtained from 1 kgm. of fresh material without shells (paper chromatographic analysis indicated that the organism contains about 150 mgm. per kgm.).

The basis of identification of the isolate was as follows. It gave taurine easily and quantitatively by oxidation with hydrogen peroxide and showed the same paper chromatographic behaviour as the synthetic 2-aminoethanesulphinic acid according to Awapara's method[4]. The R_F values between the isolated and the synthetic compounds in tertiary butanol/formic acid/water (75 : 15 : 10), normal butanol/acetic acid/water (4 : 1 : 1) and lutidine/water (75 : 25) agreed satisfactorily with each other and were 0·34, 0·21 and 0·19, respectively; these are different from those for taurine and cysteine. The elementary analysis of the isolate was C, 21·86; H, 6·48; N, 12·38; S, 29·84 per cent; the calculated values are C, 22·02; H, 6·42; N, 12·84; S, 29·36 per cent. This sulphinic acid gave the iodine–azide reaction, though it was not very sensitive, while the reaction was insensitive to taurine and sensitive to cysteine. On the other hand, cysteine reacted with alkaline sodium nitroprusside, whereas the other two did not.

It is very interesting that an easily oxidizable compound such as 2-aminoethanesulphinic acid should exist in this mollusc in relatively high content; it explains the cysteine metabolism of the organism.

Location of Alpha-2-Globulin by Demonstration of Alkaline Phosphatase during Paper Electrophoresis

ON electropapergrams, the alpha-2-globulin protein peak has been shown to coincide exactly with the locus of maximum non-specific alkaline phosphatase activity[1]. This enzyme may be detected during the run by an adaptation of the Huggins and Talalay sodium phenolphthalein phosphate method, which determines alkaline phosphatase by ascertaining the colour due to free phenolphthalein produced at *p*H 9·2 by incubating a serum sample with the colourless substrate (a blank correction is made for non-enzymatic substrate hydrolysis). Because of its broad optimum *p*H range, alkaline phosphatase has considerable activity at *p*H 8·6, which is most often used for paper electrophoresis, and a significant proportion of free phenolphthalein is coloured at this *p*H. To detect alkaline phosphatase during paper electrophoresis, 0·1–1·0 per cent of sodium phenolphthalein phosphate is included in the buffer; the region of enzymatic activity is seen as a well-localized red band. At *p*H 9·2 the band is considerably more impressive in colour.

The colour of the band reaches a maximum early in the run, which presumably means that, as free phenolphthalein is produced at the enzyme site, its ionic binding to the enzyme is disrupted by the current. Therefore, for maximum sensitivity and quantitative measurement, the strip is incubated after the run for 1 hr. at 37° C. in a moist atmosphere and then air-dried at room temperature. The phenolphthalein colour fades during drying (in our highly acid city air) but may be restored by spraying lightly with saturated trisodium phosphate. Because results with the original sodium phenolphthalein phosphate method were not linearly comparable to those of more popular techniques (Cohn, C., and Wolfson, W. Q., unpublished work), this seems likely to be

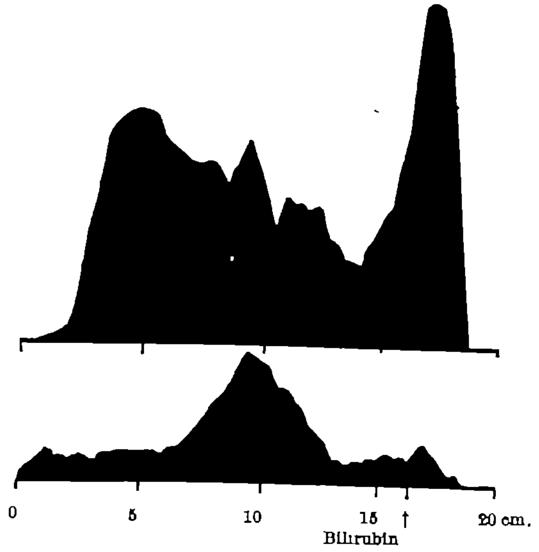

Fig. 1 Transmittance scanning curves of an electropapergram of pooled icteric serum from patients with obstructive jaundice due to intrahepatic obstruction. The sample was dried and sprayed as described in the text to give the lower curve of free phenolphthalein. For fixation it was then heated to 95° C. for a few minutes, washed with tap water to remove trisodium phosphate, and stained with amidoschwarz to determine the protein distribution and scanned to give the upper curve

true of its electropapergram modification. On the other hand, sera with elevated enzyme-levels give bands obviously more intense than do normal sera. The only critical step in the method is spraying; free phenolphthalein is very diffusible, and care must be taken not to over-spray. If the colour fades after the first spraying, one should wait until the sheet is again dry and then repeat.

I wish to thank Dr. Irving I. Young of the Department of Medicine, Wayne State University College of Medicine, whose co-operation made this study possible.

Survival of Human Circulatory Leucocytes *in vitro*: Life-span and Nucleic Acid Turnover

IT is obviously advantageous to investigate the metabolism of mammalian cells maintained as a suspension *in vitro* without previous damage to them by mechanical or enzymatic treatment. Circulatory leucocytes are eminently suitable for such a study, the more so because of their role in defence mechanisms. Most of the work done on leucocytes has been concerned with their morphology, the cells being usually derived from bone marrow and from pathological cases; and cultivation has been carried out using some solid or semi-solid supporting medium. We have been able to maintain normal circulatory leucocytes *in vitro* as a suspension for three to four days using a medium similar to that employed by Osgood *et al.*[1].

Normal blood donors were bled into a bottle containing a solution of acid-hydrolysed gelatin (intrinsic viscosity 0·13 dl./gm.) and heparin. Nine volumes of blood were taken into one volume of solution, bringing the final concentration of gelatin to 1 per cent and that of heparin to 2 units per ml. The sedimentation of erythrocytes was allowed to proceed for about an hour, plasma with white blood cells separated and spun at 220*g*. The sediment containing all the white cells with a few remaining erythrocytes (2–5 per white blood cell) was diluted with culture medium to 15,000 cells per μl. The culture medium was composed of Hanks-Simms' balanced salt solution fortified with 35 vol. per cent of pooled human serum, previously heated for ½ hr. at 56° C., glucose (100–300 mgm./100 ml.), sodium acetate (200 mgm./100 ml.), ascorbic acid (1·5 mgm./100 ml.) and penicillin (50 units per ml.). Heparin (0·5 unit per ml.) was also incorporated into this medium: heparin appears to be essential in order to prevent the cells from clumping together during subsequent incubation.

The suspension of cells was then pipetted into 100-ml. conical flasks, previously filled with 7 ml. of culture medium; each flask finally contained, in various experiments, from 3,000 to 5,000 cells per μl. All the manipulations were carried out at 0° C. under sterile conditions.

Within the first hour of incubation, some of the cells stuck to the bottom of the flask and then slipped back into the solution, forming an even, opalescent suspension. The morphological appearance and amoeboid movements were normal, as seen in the phase-contrast microscope. The flasks were incubated at 37° C. without shaking.

Table 1. GLUCOSE CONSUMPTION AND CELLULAR ESTER PHOSPHATES DURING INCUBATION OF LEUCOCYTES

Hours	Glucose in medium (mgm./100 ml.)			Ester-phosphorus in cells (μgm. phosphorus per flask)		
	1	2	3	4	5	6
0	117·3	109·9	305·5	15·1	21·4	14·8
24	99·1	69·0	270·4	7·5	13·8	9·0
48	81·6	45·7	243·6	4·2	8·2	7·6
72	71·0	35·0	238·0	2·4	6·4	4·8
96	65·8	—*	—	2·2	3·9	2·8

Each column refers to a separate experiment
* Not done.

Life-span. The nuclear count was maintained throughout incubation without marked change; this, of course, is no measure of the survival of the cells. Their morphological appearance slowly deteriorated, the number of naked nuclei and lymphocyte-like structures increasing at the expense of neutrophils.

The number of cells capable of phagocytosis, glucose consumption and the quantity of intracellular phosphate esters were determined as an index of biological activity, metabolic capacity and integrity of cytoplasm, respectively. Some of the results are shown in Table 1. The results for eight experiments are given for each consecutive day, as a percentage of the corresponding value at the start of the experiment in Fig. 1.

It is evident that the time course of the regression of all three indexes follows a similar trend, from which the half-life of a leucocyte can be estimated as 36 hr.; the average life-span under these conditions *in vitro* is therefore 25 hr. This figure agrees well with the figure of 48 hr. calculated by Osgood *et al.*[1] for segmented neutrophils from human marrow.

Phosphorus turnover. For the determination of phosphorus turnover, $Na_2H^{32}PO_4$ was added to the flasks, bringing the final activity of the medium to $0·5–1·0 \times 10^6$ counts per min. per ml. Previous to fractionation, the cells were spun down, washed once with 1 per cent acetic acid in order to remove remaining erythrocytes and denatured with 10 per cent trichloracetic acid. The fractionation was carried

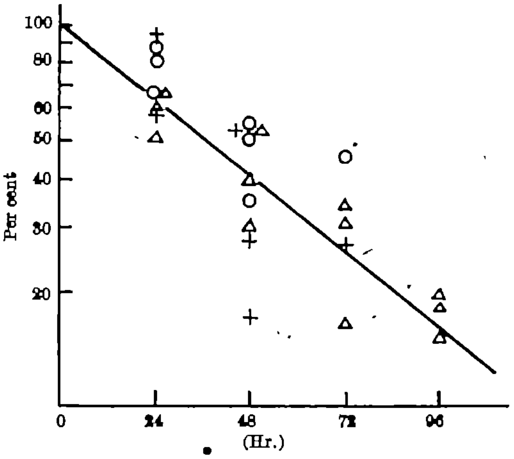

Fig. 1. Decay of leucocytes. —O—O—, Phagocytosis; —×—×—, glucose consumption; —Δ—Δ—, ester phosphates. The graph has been constructed using the method of least squares

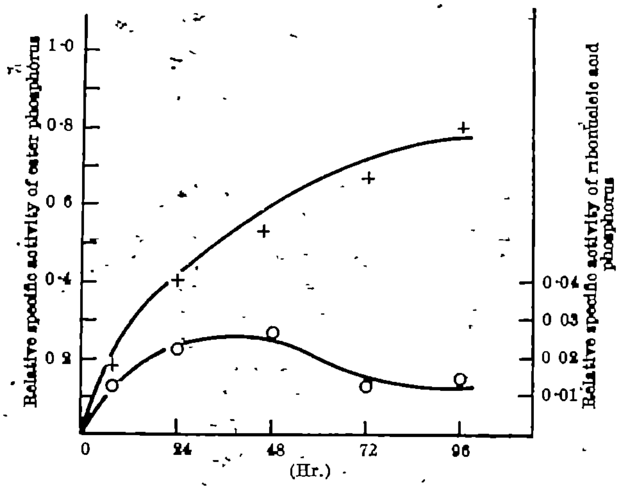

Fig. 2. Phosphorus-turnover. —+—+—, Relative specific activity of ester phosphorus; —O—O—, relative specific activity of ribonucleic acid phosphorus

out by the method of Schmidt and Tannhauser as modified by Davidson and Smellie[2]. The ester-phosphate fraction was freed of inorganic phosphate by the method of Rose and Ochoa[3]. Phosphorus was determined by the method of Berenblum and Chain[4]. The butanol extracts were dried on plastic planchettes and counted using an end-window Geiger–Müller counter and a conventional scaler; the standard deviation of counting was kept at or below 1 per cent.

Table 2 shows the results obtained in a typical experiment. It can be seen that phosphorus is being actively incorporated into both ester phosphates and ribonucleic acid. No incorporation in the deoxyribosenucleic acid was found.

Relative specific activity of ester phosphorus was calculated from the ratio of its specific activity to the specific activity of inorganic phosphate in the medium; the relative specific activity of ribonucleic acid phosphorus was calculated from the ratio of its specific activity to the specific activity of ester phosphorus. The results are shown in Fig. 2.

It can be seen that the turnover of ester phosphates is relatively slow: equilibrium with the medium is approached only after three to four days of incubation. The maximum activity of phosphorus in ribonucleic acid usually does not exceed 3–4 per cent of the specific activity of ester phosphorus and shows a peak at about the second or third day of incubation. This is a characteristic feature of all cultures, as exemplified in Table 3.

The peak of the relative specific activity of ribonucleic acid phosphorus is probably due to its metabolic inhomogeneity. It is interesting to note that the relative specific activity of ribonucleic acid phosphorus begins to decrease at about the same time as the capacity for phagocytosis drops to a very low value.

Table 2. PHOSPHORUS INCORPORATION

Hours	Specific activity (counts per min. per μgm. phosphorus)		
	Medium: Inorganic phosphorus	Cells	
		Ester phosphorus	Ribonucleic acid phosphorus
8	19,542	1,036	19·8
24	19,399	4,642	215·6
48	17,658	10,118	167·4
72	15,335	12,815	268·5
96	14,475	16,066	—

Table 3. RIBONUCLEIC ACID TURNOVER

Hours	Relative specific activity of ribonucleic acid phosphorus	
	1	2
8	0·015	0·012
24	0·030	0·046
48	0·023	0·017
72	0·022	0·021

Summarizing, this investigation shows that normal circulatory leucocytes can survive for a few days *in vitro* as a suspension; that is, in a similar state to that in which they occur *in vivo*. This opens up new possibilities for the investigation of the biochemical mechanisms underlying their role in the defence of the body.

A Difference in the Physiology of the Large Intestine between European and Indigenous Cattle in the Tropics

A QUESTION of some importance in the tropics is the reason for the superior ability of the indigenous, humped cattle, *Bos indicus* (zebus), to thrive on dry, coarse pasture compared with the European-type cattle, *Bos taurus* (grades). The differences between the two types in this respect have not been well defined or the causes intensively sought. Since the rumen microflora is readily adaptable to a particular diet, it is unlikely that the difference lies in the digestion of fibre in the rumen. Digestibility trials with the two types of animals have indicated that this may be correct and have suggested that a difference may exist in the simple gut.

It had already been found that there was a difference between the fæces of the two animals when E. Brauwer and E. J. v. Weerden[1] published their investigations on the osmotic pressure of the gut contents of grades.

We then determined freezing-point depressions and dry matters of the contents of the abomasum, three parts of the small intestine, the cæcum and three parts of the large intestine in both types of cattle. The means of the freezing-point depressions and dry matters, the differences of means and the significance of the differences are given in Table 1. These gut samples were taken within two hours of death from twenty animals of each type selected at random in a slaughter-house.

The fæces samples were taken from cattle in the field. The actual osmotic pressures and dry matters were found to vary with time and place; but when samples were collected from groups of each type

Table 1. Freezing Point Depressions and Dry Matter Percentage of the Gut Contents of *B. indicus* and *B. taurus*

	Freezing point depression				Dry matter			
	Means *B. indicus*	Means *B. taurus*	Difference of means	Significance of difference	Means *B. indicus*	Means *B. taurus*	Difference of means	Significance of difference
Abomasum	0·549	0·555	0·006	nil	—	—	—	—
Duodenum	0·912	0·874	0·038	nil	13·8	9·8	4·0	nil
Jejunum	0·917	0·969	0·052	nil	10·0	11·0	1·0	nil
Ileum	0·654	0·668	0·014	nil	8·1	8·8	0·7	nil
Caecum	0·566	0·526	0·040	nil	15·0	12·8	2·2	5 per cent
Proximal colon	0·583	0·545	0·038	5 per cent	13·8	12·3	1·5	5 per cent
Middle colon	0·511	0·463	0·048	app. 5 per cent	14·0	12·2	1·8	1 per cent
Distal colon	0·483	0·373	0·110	1 per cent	15·8	14·5	1·3	nil
Faeces, group 1	0·510	0·287	0·223	0·1 per cent	14·1	10·9	3·2	1 per cent
Faeces, group 2	0·358	0·287	0·071	5 per cent	16·1	14·1	2·0	5 per cent
Faeces, group 3	0·369	0·231	0·138	0·1 per cent	—	—	—	—
Blood	0·541	0·531	0·010	nil	—	—	—	—

grazing together or near each other at the same time, there was always a significant difference between means. The means of three groups of faecal samples are given in Table 1. Group 1 consisted of samples from six steers of each type which had been grazing together for several months. Group 2 was a repetition with this herd a few months later, and the blood samples were also taken from this herd. Group 3 was made up of ten faeces samples from a herd of each type grazing near each other at the same time on similar pasture.

Differences in freezing points and dry matter occur in the large intestinal contents and faeces, the osmotic pressures and dry matter of both being greater in zebus than grades. The results differ significantly from those of Brauwer and v. Weerden in that the faeces osmotic pressure of European cattle is lower here than the value they give. This may be due to climatic causes; but we have evidence (unpublished) that a difference between sexes exists in the properties of the faeces and may be relevant here since we obtained all our faeces samples from steers. The higher dry-matter content of the gut contents of zebus over grades may be connected through water economy with the greater tolerance of this type to hot and dry conditions.

Missing Step in Man, Monkey and Guinea Pig required for the Biosynthesis of L-Ascorbic Acid

Man, other primates and guinea pig are the only mammals that are known to be unable to synthesize L-ascorbic acid; thus they require vitamin C in their diet to prevent scurvy. The rat, a typical species that is independent of a dietary source of the vitamin, synthesizes L-ascorbic acid from D-glucose as follows[1-3]: D-glucose → D-glucuronolactone → L-gulonolactone → L-ascorbic acid. Recent studies[4-6] show that guinea pigs are unable to convert L-gulonolactone to L-ascorbic acid, a step which is catalysed in rats by enzymes present in liver. This communication reports that man and monkey also cannot convert L-gulonolactone to L-ascorbic acid.

L-Gulonolactone-1-^{14}C was incubated in homogenates of human and monkey liver and the amount of carbon-14 incorporated into L-ascorbic acid was measured by a procedure used previously[6].

Table 1. Conversion of L-Gulonolactone-1-^{14}C to L-Ascorbic Acid in Human, Monkey, Guinea Pig and Rat Liver Homogenate*

Species	No. of experiments	Average conversion (per cent)
Rat	4	8·0 ± 1·9†
Man‡	3	< 0·07
Monkey	2	< 0·07
Guinea pig	3	< 0·05

* Experimental conditions and procedure for isolation of L-ascorbic acid were same as those used previously (ref. 6).

† Average deviation.

‡ Samples of human liver were obtained by surgical biopsy.

In Table 1 the results of these experiments are compared with those obtained previously for rats and guinea pigs[6]. Appreciable incorporation of carbon-14 into L-ascorbic acid was observed in rat liver but none was detected in human, monkey and guinea pig liver; values being less than one one-hundredth those obtained in rats. Finding that man, monkey and guinea pig are unable to convert L-gulonolactone to L-ascorbic acid points out the biochemical step missing in the liver of these species required for the biosynthesis of L-ascorbic acid. (Unpublished observations show conversion of D-glucuronolactone-6-^{14}C to labelled L-gulonic acid in monkey, guinea pig and rat liver. The occurrence of this reaction in guinea pig and rat liver was suggested initially from enzymatic studies of ul Hassan and Lehninger[4].)

The Sex-linked Difference in Rabbit Neutrophils

IN most of the laboratory animals, including the mouse, rat, hamster, guinea pig and rabbit, the sex chromatin discovered by Barr and his co-workers cannot clearly be demonstrated in the tissue cell nuclei[1]. Lüers, however, reported a sex difference in rabbit neutrophil polymorphonuclear leucocytes, comparable to the one Davidson and Smith had already described in the human, where the female sex is characterized by the presence of a 'drumstick' appendage of the nucleus in a small and variable percentage of the neutrophils[2,3].

We are able to confirm this finding. However, in view of the heavily staining, granular cytoplasm of rabbit neutrophils, we abandoned the Pappenheim stain used by Lüers for a simpler colouring method with Harris's alum hæmatoxylin, acidified or not with glacial acetic acid (1 per cent) and diluted with distilled water (50 per cent). It is an essential part of the Papanicolaou staining method, which gave us very good results in the cytological and sex chromatin study of vaginal and urethral smears[4]. The stain is commercially available or may be prepared according to the well-known formula[5]. The blood films should be made thin and even, and allowed to dry at the air. They are put in the hæmatoxylin for two to three minutes, rinsed three times in distilled or tap water, blotted with filter paper and dried. They may be studied at once, using the immersion objective.

The red blood cells and the leucocyte cytoplasm are but faintly coloured, while the nuclear chromatin structures stand out sharply, occasionally allowing the observation of some hitherto undescribed details of the peculiar drumstick appendage. In many instances, the centre of the drumstick head appears lighter than its circumference to the point of resembling a hole. Some pattern may be interpreted as a transition towards a still more occasional morphological peculiarity, consisting in the more or less pronounced splitting up of the drumstick in two juxtaposed oblong chromatin formations (Fig. 1,e).

After preliminary trials a total of seventy-four blood smears, numbered in random order and registered by an assistant, were obtained from fifteen male and twenty-one female rabbits of five different breeds.

In the blood smears of female rabbits, the typical drumstick was found in an unexpectedly high proportion of the neutrophil leucocytes. We made a distinction between 'certain' drumsticks, lying completely free from other nuclear structures, and therefore well outlined and entirely typical, and 'probable' drumsticks, which were still recognizable, but not entirely outlined, being sessile or slightly superposed on the rest of the nucleus. Every other strongly suggestive structure in this sense was called 'possible' drumstick. By studying no more than twenty neutrophils in each smear, it was possible to determine exactly in all instances the sex of the unknown donor animal. Only in one male rabbit was a 'probable' drumstick found and the count continued to thirty neutrophils for the sake of safety. In no single instance was a 'certain' drumstick found in the blood smear of the male animal. The numerical results of this study are summarized in Table 1.

Table 1

Sex of rabbits	Female	Male
Number of blood smears	41	33
Total of neutrophils studied	820	670
Number of 'certain' drumsticks	156 (19 per cent)	0
Number of 'probable' drumsticks	66 (8 per cent)	1 (0·15 per cent)
Number of 'possible' drumsticks'	68 (8 per cent)	19 (3 per cent)

The frequency of drumsticks in the female rabbit blood smears, studied with our technique, approaches 20 per cent, the highest mean value hitherto described in any species. In fact, with some experience and accepting that no typical drumstick ever occurs in the male rabbit blood smear, counting—a cumbersome drawback of similar studies in the human—is no longer essential.

The remarkable work of Jost on the role of the fœtal testis in genital development[6] was convincingly supported by the discovery of the sex chromatin and its study in cases of human sexual malformation[7]. Most of this work was performed on rabbits—in this respect very suitable experimental animals. Simple and accurate determination of their blood sex type opens still further research possibilities. It was advanced by Briggs and Kupperman that endocrine factors have a bearing on the incidence of the drumstick in the human female[8]. Von Harnack and Strietzel directed attention to the higher incidence in premature and newborn babies of female sex[9]. The rabbit might be an animal of choice in the experimental investigation of this problem.

It has been generally assumed that the sex chromatin body is derived from (heteropycnotic portions of) the chromosome complex, *XX*, and that the drumsticks are constituted by sex chromatin. For these assumptions direct proof is still lacking, but a lot of indirect evidence has been assembled, some of which seems to be confirmed by our observations. The splitting-up phenomenon in drumsticks immediately reminded us of the studies of Crouch and Barr on female cat's neurons during axon reaction[10]. They occasionally observed a bipartite sex chromatin body, appearing "similar to a diplo-

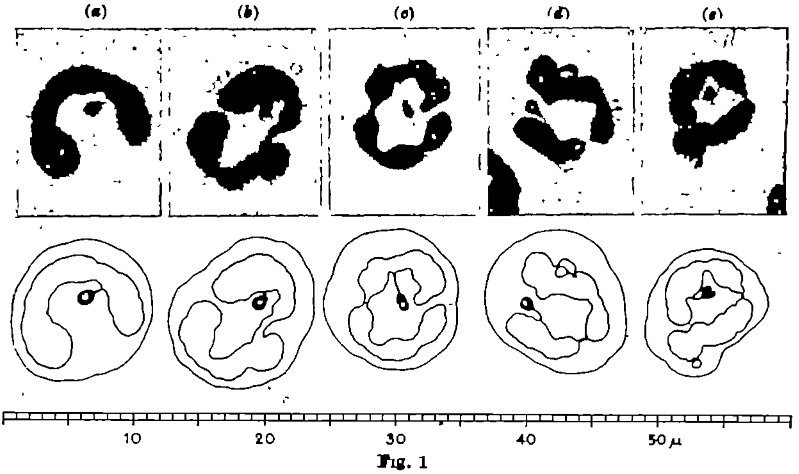

Fig. 1

coccus" and presumably derived from the two X-chromosomes. In another study, Moore and Barr gave a similar explanation of the minute pale area observed within the sex chromatin corpuscle[11]. Of course, completely analogous views may be held as to the structural details of rabbit drumsticks, reported above. Ranging from those with a central hole to those with a frankly split-up aspect, a continuous series of drumsticks with increasingly bifid character can be constituted (Fig. 1,*a*–*e*). A bipartite composition of the drumstick and an intimate relationship to the XX-chromosome-complex and to (intranuclear) sex chromatin is therefore strongly suggested. The drumstick may thus tentatively be considered as a sex chromatin body, characteristically bulging out of the nucleus in some of the neutrophil leucocytes.

Preliminary observations indicate that with the staining method indicated above, similar details may also be observed in human drumsticks.

We wish to express our thankful appreciation to Mr. P. Spaan for assistance and to Mr. A. Reijnen and Mr. Ch. Van Huijzen for preparing the illustration.

Effects of Molybdenum and Copper on some Enzymes in *Neurospora*

It is well established that copper and molybdenum are reciprocally antagonistic in animal metabolism; but the causal mechanism is not known[1]. Zinc toxicity in the rat has been shown to deplete liver catalase and cytochrome oxidase, which were restored to normal levels by incorporating small amounts of copper sulphate in the diet[2].

In a factorial experiment we have determined the effects of copper and molybdenum at deficient, optimal and toxic levels (based on dry-weight yields of the felts) in the basal medium on a range of enzymes in *Neurospora*. The results show that the effect of molybdenum at toxic levels in depressing some enzymes can be alleviated by increasing copper and vice versa. Other enzymes reduced by toxic levels of copper or molybdenum were either not restored or were depressed further by increasing the other metal in the medium. Thus cytochrome *c* oxidase and its reductase, depressed by molybdenum excess, were partially reconstituted by increasing copper whereas the reverse relationship was found for nitrate reductase. Acid phosphatase, reduced by molybdenum toxicity, was not corrected by copper treatment. The diaphorase of reduced triphosphopyridine nucleotide was decreased by high copper levels irrespective of the molybdenum status. Nitrite reductase was depressed either by molybdenum or copper at toxic levels whereas catalase, reduced diphosphopyridine nucleotide diaphorase and alkaline phosphatase were unaffected at any level or combination of the two metals employed in the experiments.

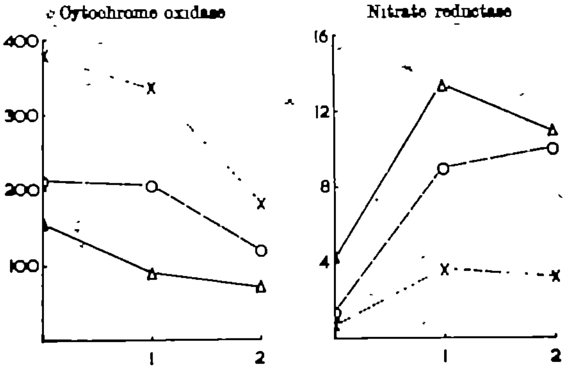

Fig. 1. The effects of copper and molybdenum on cytochrome oxidase and nitrate reductase. Abscissa: cytochrome oxidase, change in log I_0/I_1 of 0·001/min./mgm protein or nitrate reductase, mμM NO_2/10 min./mgm. protein; Ordinate: molybdenum treatments. Δ, Cu_0; ○, Cu_1; ×, Cu_2. (Copper and molybdenum treatments as in Table 1)

Neurospora crassa macroconidial wild type 5297*a* was grown in a modified Fries medium with sodium nitrate as the sole source of nitrogen[3], and molybdenum and copper were removed from the basal culture solution by methods described previously[4]. Molybdenum (sodium molybdate) was supplied at 0–0·004, or 40 mgm., and copper (copper sulphate) at 0–0·016 or 2 mgm. in 200 ml. culture solution contained in 1-litre Erlenmeyer flasks. The three replicates for each treatment were randomized in the incubator, and after four days growth in the dark at 30° C. the felts from the same treatment, collected in a Büchner funnel, were well washed with glass-distilled water and put in a deep-freeze unit at − 17° C. for 12 hr. The felts were then ground with four times their weight of 0·1 M phosphate buffer (pH 7·5) in a cold mortar and then in a Ten Broeck

Table 1. EFFECTS OF COPPER AND MOLYBDENUM TREATMENTS ON REDUCED TRIPHOSPHOPYRIDINE NUCLEOTIDE DIAPHORASE AND ACID PHOSPHATASE (ENZYME UNITS, SEE REF. 3)

Mo_1	0·004	Cu_1	0·016
Mo_2	40·0	Cu_2	2·0

glass macerater at 0° C. The homogenates were centrifuged in the cold for 10 min. at 3,000*g*. Catalase, peroxidase, cytochrome *c* oxidase and reductase, nitrate and nitrite reductases, reduced di- and tri-phosphopyridine nucleotide diaphorases, acid and alkaline phosphatases were assayed in the supernatant solutions[4]. Protein was determined by Folin's method. The enzyme units are expressed per mgm. protein.

The interactions of copper and molybdenum on the activities of cytochrome oxidase and nitrate reductase are illustrated in Fig. 1. Increasing copper from deficient to toxic levels enhanced the activity of cytochrome *c* oxidase; but this effect was much reduced when molybdenum was increased to toxic levels. A similar result was obtained for cytochrome *c* reductase. The reverse effect is shown by nitrate reductase, a molybdo-flavoprotein[5]; increasing molybdenum from deficiency to sufficiency stimulated its activity whereas copper depressed it.

The results for acid phosphatase and reduced triphosphopyridine nucleotide diaphorase are given in Table 1. The phosphatase was depressed by increasing molybdenum from deficiency to toxicity levels and an increase in copper did not significantly offset it. The reverse effect was found for the diaphorase activity which was inhibited by the highest copper treatment, and this was not significantly overcome by increasing molybdenum. Nitrite reductase was depressed when either copper or molybdenum was in excess. Although the overall effects of the two metals on catalase, peroxidase and alkaline phosphatase or the reduced diphosphopyridine nucleotide diaphorase were not significant, a deficiency of molybdenum depleted the two iron enzymes, as observed previously[6].

It appears that the nutrient antagonisms in nutrition experiments may be related to their effects on certain enzyme systems as illustrated here for copper and molybdenum in *Neurospora*. A full account of this work will appear in the *Journal of General Microbiology*.

Note added in proof. Subsequent experiments have shown that molybdenum competitively inhibits acid phosphatase *in vitro* presumably by forming a molybdo-phosphate addition compound with the substrate. Copper dispersed this complex and restored the enzyme activity to normal. Vanadate or tungstate had a similar inhibitory effect to molybdate on the enzyme activity, which was also reversed by adding copper.

Radiosensitivity of Salt Uptake in Plants

SOME investigations[1] of the effects of radioisotopes absorbed by plants have suggested that the mechanism of salt uptake is sensitive to low doses of ionizing radiations. It is impossible, however, in such experiments to make precise estimates of the dose to which the tissues are exposed. This uncertainty can be overcome by exposing plants to external sources of radiation.

In the experiments reported here, aerated suspensions of *Chlorella pyrenoidosa* (Emerson strain) in 0·005 *M* solutions of rubidium chloride, containing tracer amounts of rubidium-86, were exposed to doses of 50–1,000 r. of 240-kV. X-rays, during a 60-min. period. The *Chlorella* was then separated from the active solution and resuspended in an aerated 0·01 *M* solution of rubidium-85 chloride, and exchange was allowed to continue for 60 min. By this means the rubidium-86 taken up was separated arbitrarily into two fractions: that which was readily exchangeable with rubidium-85, consisting of ions which were freely diffusible or held in Donnan systems and by other exchange mechanisms, and a second fraction which was non-exchangeable under the experimental conditions. This latter fraction would include ions that had undergone active transport. Solutions were counted in an *M*.6 liquid counter. In all experiments there were five treatment replicates and five controls.

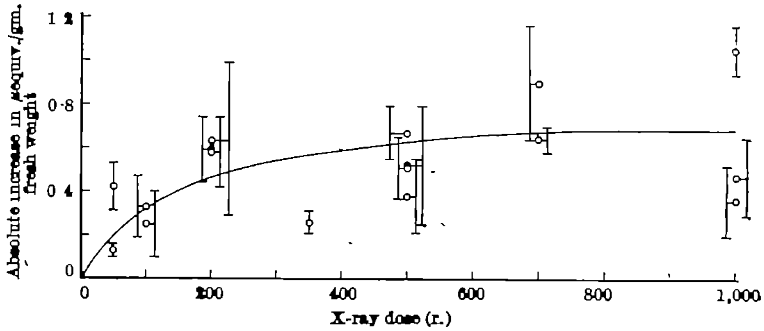

Fig. 1. Depression of non-exchangeable uptake induced by X-irradiation in *Chlorella pyrenoidosa*

At none of the doses used was there any significant effect upon the amount of readily exchangeable ion, but at all dose-levels there was a significant decrease in the amount of non-exchangeable ion as compared with the uptake by the unirradiated controls. In Fig. 1 the absolute decrease in uptake is plotted for the various dose-rates. There was very little increase in the effects of X-rays between 200r. and 1,000r.

It should be noted that the *Chlorella* stocks used in this work could not be grown under absolutely constant conditions; thus the rate of salt uptake by the unirradiated controls varied between experiments. In Table 1 the results for the experiments at 200r. and 500r. shown in Fig. 1 are examined in greater detail. It is seen that although the percentage decrease varied at both dose-levels, the absolute reduction in absorption induced by radiation was relatively constant.

It is suggested that this observation may in part explain the widely varying effects of the radiations from tracers on salt uptake which have been reported hitherto. A full report of this investigation, which is

Occurrence of Motile Gametes in *Prasiola stipitata* Suhr*

THE apparent absence of sexual reproduction in the Prasiolaceae has been one of the notable features of this family. It was of considerable interest, therefore, when two decades ago, Yabe[1] announced that sexual reproduction occurs in the freshwater species *Prasiola japonica* Yatabe and is effected by the fusion of anisogamous biflagellated gametes. Fujiyama[2,3], also using material of *P. japonica*, has confirmed Yabe's observations in the main essentials, except that he considers the female gamete to be non-motile. For all that, doubts about the sexual reproduction of *Prasiola* have been expressed quite recently by Fritsch[4] and Smith[5], although Fujiyama's second paper could not have been seen by these authors at the time they wrote.

As a result of observations on the marine species, *P. stipitata* Suhr, we are able to confirm the occurrence of motile anisogamous gametes in this genus. The senior author first distinguished the gametophytes among material collected at Bangor, North Wales, in February 1955; but it was not until February of the following year that she was able to verify the motility and fusion of the gametes. In view of the interest of these observations, a detailed investigation of the development and life-history of this species has since been undertaken by the junior author, who has also studied the gametes and fusion in greater detail.

Gametophytic thalli of *P. stipitata* are common in the winter months and are easily recognized by their conspicuous patchwork appearance (Fig. 1). This is due to mixed darker areas from which female gametes are liberated and much paler areas from which come the male gametes. For every female portion of the thallus there is a corresponding and contiguous male portion. The size of individual areas, and accordingly the number of gametes formed in them, vary greatly in different thalli and even within the same thallus. While the vegetative parts of the thallus are monostromatic, in the gamete-forming portions the thallus is polystromatic, usually four-layered in the female and eight-layered in the male areas. The gametes mature basipetally and are liberated periodically. Both gametes are broadly guttiform and bear, at their pointed anterior end, two isokontan flagella of the whiplash type (Fig. 2*a*, *b*). The flagella of the female gamete are much longer than those of the male.

Immersing dry thalli induces liberation of mature gametes, and fusion follows very soon afterwards. In the instances observed, fusion has been limited to gametes of the same thallus isolated on microscope slides or culture dishes. On the other hand, it would be difficult, without very elaborate technique, to prove fusion between gametes from different thalli. Female gametes usually lose one flagellum before fusion, which begins at the anterior end of the gametes (Fig. 2*c*). Apparently, both flagella of the male gamete are lost at the time of fusion as the zygote has a single flagellum which, on account of its length, must belong to the female gamete. Sometimes the basal remnants of the male flagella can be seen attached to the zygote. After a short period of motility, the pear-shaped zygote (Fig. 2*d*) loses its flagellum and becomes rounded.

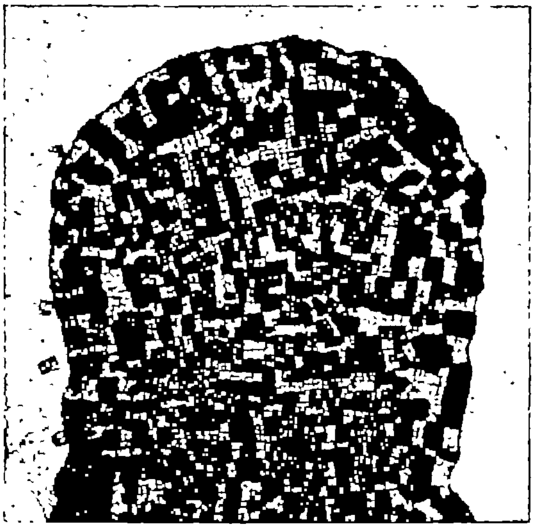

Fig. 1. Upper portion of a gametophytic thallus of *Prasiola stipitata* Suhr, showing darker areas of the female gametes and paler ones of the male gametes. Photographed living. × 90

---

* Although this specific name may not be the valid one for the species concerned, being in general use, it is retained until certain taxonomic and nomenclatural questions have been settled.

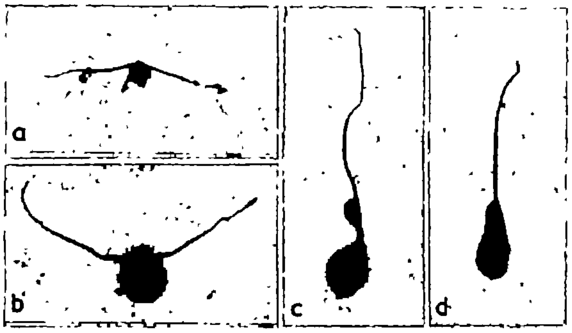

Fig. 2. Gametes and zygotes of *Prasiola stipitata* Suhr. *a*, Male gamete; *b*, female gamete; *c*, gametic fusion; *d*, motile zygote. All photographed after staining by Kirkpatrick's method. × 1,250

The gametes and zygote in Fig. 2 have been fixed in fumes of osmic acid and have been stained by Kirkpatrick's method as modified by Manton[6].

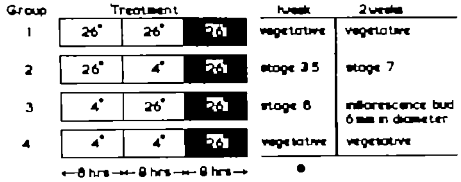
Flowering of *Xanthium* under Long-Day Conditions

Efforts to induce flowering in the short-day plant *Xanthium pensylvanicum* under long-day conditions have consistently failed up to now. From numerous reports it has been concluded that for flower induction a short photoperiod must be followed by a long night. The role of the short photoperiod seems to be the photosynthetic production of energy substrates, since it can be substituted for it by sugar treatment[1]. An uninterrupted long dark period of 9 hr. or more is considered to be necessary to build up a minimum amount of 'flower stimulus'. However, in *Perilla*, also a short-day plant, the long-night requirement was alleviated by exposing the plants to a low light-intensity during the day[2]. Furthermore, a low-temperature treatment during part of the long photoperiod was found to promote flowering (Wellensiek, private correspondence). Thus it appeared worth while to study the effect of low light-intensity and of low temperature during a long photoperiod on the flowering response in *Xanthium*.



Group	Treatment			Dissection after 1 week	2 weeks
1	26°	26°	26	vegetative	vegetative
2	26°	4°	26	stage 3.5	stage 7
3	4°	26°	26	stage 6	inflorescence bud 6 mm in diameter
4	4°	4°	26	vegetative	vegetative

Fig. 1. The influence of different temperatures during the long photoperiod on the flowering response in *Xanthium*

Experiments on the influence of a low light-intensity during a 16-hr. photoperiod on flowering were completely negative. No flowering occurred. *Xanthium* requires a high light-intensity period for its flower induction. In addition, a low light-intensity during the short photoperiod (8 hr.) delayed flowering considerably. From dissection of the terminal buds, it was concluded that this delay was not due to postponed induction but to a slower development of the flower primordia. This again supports the idea that in *Xanthium*, in contrast to *Perilla*, flowering is only possible when a relatively large amount of energy is available. Given this amount of energy, the question remains whether a long-night period is obligatory for flowering or not.

It is known that small amounts of light or a low temperature during the dark period render this period in short-day plants ineffective. A low temperature during the short light-period does not affect flowering very much. But what is the effect of light at low temperature, provided that enough light at high temperature has been given to meet the high light-intensity requirement of *Xanthium*? Does this light prevent flowering, or does it act, in a physiological sense, as darkness?

To investigate this effect, the following experiments were set up in the Earhart Laboratory at Pasadena, California. Plants grown under long-day conditions (light-intensity ± 1,000 f.c.) until they had three or four mature leaves were exposed to a 16-hr. photoperiod, half of which was at 26° C. and half at 4° C.; the dark period (8 hr.) was given at 26° C. In one group the low temperature was given just before the dark period, and in the other just after the dark period (see Fig. 1). The treatment lasted four days, after which the plants were put under normal long-day conditions. Each treatment included twenty plants, half of which were dissected at one week and the other half two weeks after treatment. A suitable measure of rate of growth of inflorescence bud was found to be that developed by Salisbury[3].

The results (see Fig. 1) indicate that: (1) flower initiation under long-day conditions is possible; (2) flower initiation is, qualitatively, not dependent on the time of the low-temperature treatment during the light period; (3) the flowering response is much larger when the low-temperature period precedes the high-temperature period.

In another experiment the same treatments were given, but for two days only. The plants responded in the same way, although less markedly. After two weeks, the terminal buds of group 2 were just starting to become generative (stage 1.8), whereas those of group 3 had already reached stage 6. The controls were completely vegetative.

It is evident from these experiments that for flowering there is no absolute requirement for a 9-hr. dark period in *Xanthium*. More work has still to be done to elucidate the relation between light at low temperature and darkness.

I am indebted to Dr. F. W. Went for his hospitality and co-operation.

Distribution of Chiasmata in an 'Asynaptic' Locust

The relationship between the length of the chromosomes and the frequency with which they form chiasmata at meiosis is well known and has been analysed extensively by Darlington[1], Mather[2] and others. In general, it is found that long chromosomes form more chiasmata than short chromosomes in the same nucleus. The chiasma frequency, however, is not always found to be directly proportional to length, that is, the potential for forming chiasmata varies between chromosomes to some degree independently of their length. The details of such variation could be investigated in most favourable circumstances during observations made in *Locusta migratoria*. These are briefly described below.

An exceptional male in one family was found with an abnormally low chiasma frequency at meiosis during which univalents appeared in a high proportion of spermatocytes. This example of asynapsis is, so far as I know, the first recorded for this species. Because the chromosomes can be classified into groups of different lengths the relative frequencies with which they form, or fail to form, chiasmata under these conditions can readily be ascertained for the chromosomes in different groups. In the male locust there are eleven pairs of autosomes and one *X*. The classification and measurements, after Mather[3], are given in Table 1.

Table 1

Chromosome pairs	*L*(2)	*LM*(1)	*M*(5)	*S*(3)
Length in μ	5·3	3·9	2·9	1·2

In the asynaptic and other males in this family there were supernumerary chromosomes in a proportion of the spermatocytes[4]. These had no detectable influence on the chiasma frequency.

The diplotene chiasma frequencies of the asynaptic male are plotted against chromosome-length in the graph. Also plotted, for comparison, are the chiasma frequencies in a normal sib. It will be seen that the response to the abnormal, probably genotypically determined, conditions causing asynapsis is not the same for all classes of chromosomes. The reduction in chiasma frequency is relatively much greater in the *L* and *LM* chromosomes than in the *M* and, in particular, the *S* chromosomes. A further comparison suggests more precisely how the differences between the groups arise. This comparison takes into account the frequencies with which their members completely fail to form chiasmata, that is, produce univalents. The data are given in Table 2.

Table 2. CHIASMA FREQUENCY

	Less than one	One or more
L	12	38
LM	7	18
M	12	118
S	2	73

We see that only exceptionally are the *S* chromosomes unable to form at least one chiasma in the asynaptic male. As the graph (Fig. 1) shows, their average, about 1, is virtually the same in both normal and asynaptic individuals. The longer chromosomes, on the other hand, fail to form one chiasma with a significantly higher frequency ($P = < 0{\cdot}01$). This, as distinct from their forming fewer chiasmata over and above one, accounts for a large part of the reduction in their chiasma frequencies.

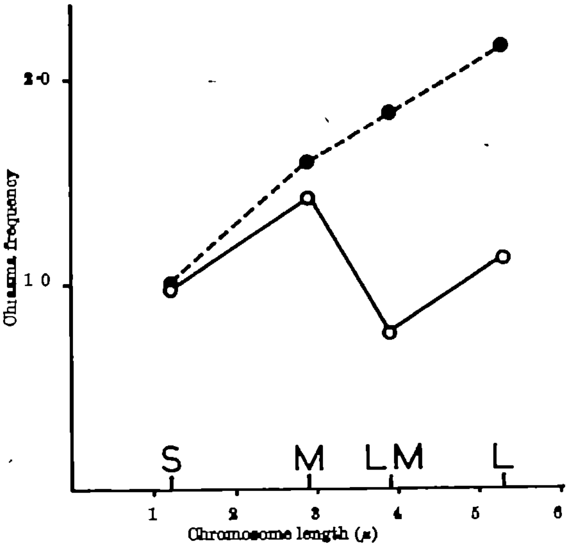

Fig. 1. The chiasma frequencies at diplotene plotted against chromosome-length in an asynaptic and a normal male locust. Data from thirty-five cells in each. Asynaptic, ○ ; normal, ●

From the earlier results[1,2], based mainly on observations in normal diploids of a number of species, it was concluded that short chromosomes were endowed with special, distinctive, properties in respect of their ability to form at least one chiasma during meiosis. The disproportionately high frequencies with which the longer chromosomes form univalents under the conditions of asynapsis described above confirm this conclusion in a decisive fashion. No doubt, as the earlier authors suggested, the difference between long and short chromosomes is adaptive, securing, in normal circumstances, regular pairing within nuclei the chromosomes of which vary widely in length, and where, as in locust, the average chiasma frequency per bivalent is comparatively low.

Changes in Response to Light Stimuli of the Larvæ of *Culicoides circumscriptus*

When the larvæ of *Culicoides circumscriptus* are extracted from the mud of their natural habitat the great majority exhibit a negative phototaxis. If they are kept in water without food over a period of time many become positively phototactic. The percentage of larvæ which undergo this reversal increases rapidly for 6–7 days and thereafter remains fairly constant at a level of between 60 and 90 per cent of their total number.

If food is given to the larvæ at this stage there follows a sudden drop in the proportion of photopositive individuals. In some experiments the food given consisted of chopped-up blowfly larvæ, which is not the natural food of the larvæ of this species of *Culicoides* and, after the initial drop, the proportion of photopositive larvæ rose again to the level reached before feeding, this in spite of their being supplied daily with fresh food. If, however, starved photopositive larvæ are put into mud rich in living organic matter this does not happen, and the curve continues to fall until a level of between 20 and 30 per cent is reached and maintained. Conversely, if starved photopositive larvæ are placed in a medium containing no live organic matter no reversion to photophobic behaviour takes place.

These experiments show that the behaviour of the larvæ of *Culicoides circumscriptus* towards light stimuli is greatly affected by hunger. This conclusion is also supported by the fact that the proportion of photonegative larvæ which show evidence of having fed is generally significantly greater than of those which showed a photopositive taxis.

The phenomenon of change of taxis has proved to be a useful tool to determine the types of material on which these larvæ will feed. If the material offered to starving photopositive larvæ is wholly suitable for their requirements the majority revert to photophobic behaviour as long as food is available; but if the food is inedible or non-nutritious there is no change of taxis. If the food is edible but inadequate for nutritional requirements the larvæ exhibit only a temporary reversion to negative phototaxis.

It is possible that this method of determining food requirements may be applied to a number of different animals but much depends on the habits and environment of the species concerned. In *C. maritimus*, a species living in the same habitat as *C. circumscriptus* but in a different niche and with apparently different feeding habits, the changes in response to light stimuli are not sufficiently clearly defined for this method to be used.

The above experiments will be more fully described and their significance discussed in a paper to be published in the near future.

Feeding Habits of a Marine Centipede

During a night collecting expedition on the shore at Port Erin, Isle of Man, a party of students, accompanied by Dr. Iles and myself, came across a rather unusual association of predator and prey. The predator was the common littoral geophilomorph, *Scolioplanes maritimus* (Leach), and its food consisted of barnacles (*Balanus balanoides* (Linné)) and periwinkles (*Littorina saxatilis* (Olivi)).

The centipede is common all around the British coast; but a particularly thriving colony has been under observation at Port Erin for several years. The animals inhabit coarse shale between mid-tide level and high-water mark during the hours of daylight; but at night they are to be seen on an adjacent rock face and concrete wall with barnacles on the face and periwinkles in the cracks and fissures.

On the first occasion, at about 10 p.m., the hind-ends of three centipedes were seen projecting from between the opercular plates of an apparently intact barnacle. The animals did not react to the light of a torch but rapidly extricated themselves when touched. The slit between the opercular plates was apparently just sufficiently wide to allow the strap-shaped centipedes to enter or leave. The soft parts of the barnacles had been reduced to a slimy consistency suggesting extra-intestinal digestion.

On the first night two barnacles were seen, each providing a meal for three centipedes. This was an hour or two before high tide. Later in the week, with the advancing time of high tide, we were able to keep the animals under observation as the tide receded from the area, for several nights, all of which were moonlit. As many as twelve centipedes were seen feeding in an area roughly two square metres on the concrete wall and many others on the rock face, where counting was more difficult, the animals being disturbed more easily by movement of seaweed, etc. Adults of both sexes, together with immature stadia, were involved. Progressively later visits on the same night revealed a higher proportion of animals feeding as opposed to just walking around and a greater aggregation of the feeding animals—the maximum number observed on any one barnacle being six.

On fewer occasions, centipedes were seen feeding on *Littorina saxatilis*. One centipede had its head completely hidden in a periwinkle which had become dislodged from the wall and was swinging pendulum-fashion on the end of the centipede. The centipede was anchored to the wall by no more than four or five of its hindermost pairs of legs.

No centipede was caught in the act of making the initial entry into either a barnacle or a periwinkle, since the torchlight caused the animals to move rapidly away from the illuminated area. At first sight, the business of entering the prey would appear hazardous in the extreme; do the centipedes immobilize the closing mechanisms of their prey by means of the poison claws, or is the closure not sufficiently tight to do them harm? The size of aperture through which a geophilomorph can pass is amazingly small, and we noticed that a small gap always exists between the plates of the barnacle, which latter only close tightly on strong mechanical stimulation. The periwinkles are not closed at night, of course, but are actively feeding.

Surface Properties of Sodium Octyl Sulphate in Saturated Salt Solutions

As part of a study of the flotation of soluble salts the surface tension of sodium octyl sulphate has been measured[1] in saturated solutions of lithium, sodium, potassium and ammonium chlorides at 20° C. No previous measurements are recorded for the surface tension of sodium octyl sulphate in saturated salt solutions or in water. This compound has very little effect on the surface tension in water, but in the saturated salt solutions the maximum lowering of surface tension is approximately 50 dynes cm.$^{-1}$.

The measurements were made by the drop-volume technique and the surface tension calculated by applying the corrections of Harkins and Brown[2]. For temperature control the 'Agla' syringe was enclosed in a thermostated jacket and the whole assembly placed in a water bath (unpublished work by H. C. Parreira). The sodium octyl sulphate was tested for purity by paper chromatography and found free from higher homologues. The chlorides were of analytical reagent quality, except the lithium chloride. Solutions of sodium octyl sulphate were prepared in two ways to ensure that equilibrium was obtained. Either known weights of crystals of octyl sulphate were shaken with measured volumes of saturated salt solution at 20° C., or the required amount of salt, freshly dried at 110° C., was weighed into a standard flask to which distilled water and aliquots of a 10^{-2} molar aqueous solution of octyl sulphate were added.

In the saturated salt solutions no changes of surface tension with time were found. In water ageing effects[3] are important, but have been shown to disappear if salt is added[4]. Possible effects of small amounts of calcium and barium[5] were investigated by adding to (analytical reagent) ammonium chloride 0·005 per cent Ba^{++} as barium chloride and 0·01 per cent Ca^{++} as calcium chloride. No effect was found. Experiments with (analytical reagent) sodium chloride purified by double precipitation did not show any differences from the surface tensions obtained with unpurified salt.

In Fig. 1 the surface pressures are plotted against the logarithm of the concentration of sodium octyl sulphate in saturated sodium, potassium and ammonium chloride solutions. Lithium chloride is so soluble that in saturated solution the sodium octyl sulphate did not dissolve. In Fig. 2 the area occupied by the octyl sulphate molecules is plotted as a function of surface pressure. The areas were calculated from the equation[6] $d\pi = \Gamma RT\, d \ln c$, where π is surface pressure, Γ the surface excess concentration, and c is the bulk concentration of sodium octyl sulphate.

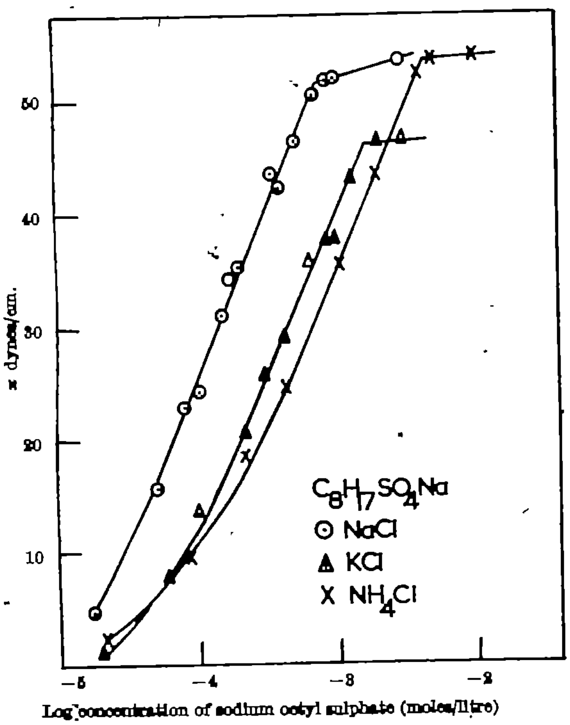

Fig. 1

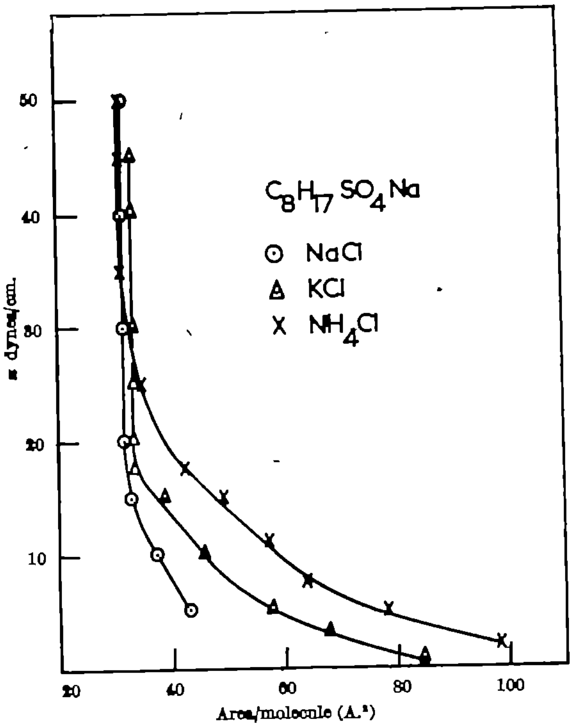

Fig. 2

Fig. 2 shows that the expansion of the octyl sulphate film is related to the size of the anhydrous counter-ion in the solution. The radii of ammonium, potassium and sodium ions are 1·43, 1·33 and 0·95 A. respectively. The film is most expanded for ammonium chloride and least in sodium chloride. The curves are not related to the solubility, or activity, of the inorganic salts. The correlation of area per molecule with ionic size of the counter ion has been noted[7] for insoluble films of octadecyl sulphate on solutions of lithium, sodium, potassium and ammonium chlorides of equal activity (6·7). However, for the insoluble films the radii of the hydrated ions is significant so that expansion of the film decreased from lithium chloride in the order sodium, ammonium and potassium chloride.

We are indebted to Dr. J. H. Schulman for stimulating discussion and interest in this work, which was made possible by grants from the Consolidated Zinc Corporation, Ltd., and the Ernest Oppenheimer Endowment.

FORTHCOMING EVENTS

Monday, September 16—Friday, September 20

Society for Experimental Biology (at University College, Gower Street, London, W.C.1)—Symposium on "The Biological Replication of Macromolecules".

Friday, September 20

Biochemical Society (in the Department of Biochemistry, Queen's College, Dundee), at 10.30 a.m.—Scientific Papers.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Experimental Officer or Experimental Officer (with a pass degree in science) for work in the Biochemical Laboratory—The Secretary, Plant Breeding Institute, Trumpington, Cambridge (September 20).

Assistant in the Department of Chemistry—The Secretary, The University, Aberdeen (September 20).

Lecturer (with good academic qualifications and industrial experience) in Organic Chemistry, to teach organic chemistry up to Part II, Royal Institute of Chemistry examination standard—The Registrar, Flintshire Technical College, Connah's Quay, Chester (September 21).

Technical Assistant (preferably with a university degree, or equivalent qualification, in engineering or physics, with the ability to apply a sound knowledge of physics and mathematics to practical problems; an interest in instrumentation and electronics and knowledge of the use of tools for such purposes would be an advantage), for a programme of research on new developments in the use of electricity—The Secretary (Establishments Section), South Wales Electricity Board, St. Mellons, Cardiff (September 24).

Lecturer (preferably with special interests in high frequency techniques or in servomechanisms) in Electrical Engineering—The Principal, Manchester College of Science and Technology, Manchester 1 (September 30).

Lecturer (able to carry out independent research and to supervise the work of postgraduate students) in Theoretical Physics—The Registrar (Room 9 O.R.B.), The University, Reading (September 30).

Principal (with a university degree in science or engineering, or equivalent qualification, and experience in responsible posts in technical education) of Belize Technical College, British Honduras, for duties including advising the Government on technical education—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting BCD.114/31/04 (October 4).

Assistant Lecturer or Lecturer (with a degree in pure science) in Agricultural Zoology at the Canterbury Agricultural College, New Zealand, to teach pure and applied zoology for the degree and diploma courses in agriculture and horticulture, and to carry out research in agricultural zoology—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (October 15).

Lecturer or Assistant Lecturer in Mathematics at the University of Otago, Dunedin, New Zealand—Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (October 15).

Lecturer (with an honours degree in mathematics) in Mathematics in the Department of External Studies, University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (October 18).

Lecturer (preferably graduate in agricultured science or civil engineering, with experience in soil genesis or plant nutrition or mechanical properties of soils) in Agriculture (Soil Science) at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (October 19).

Analyst, Scientific Officer or Senior Scientific Officer grade (with a first- or second-class honours degree and suitable analytical experience), for the British West Indies Sugar Research Scheme, Imperial College of Tropical Agriculture, Trinidad, for work mainly on devising new analytical techniques over a wide field—The Secretary, The Imperial College of Tropical Agriculture, 40 Norfolk Street, London, W.C.2 (October 31).

Keeper and Lecturer in Anthropology, joint appointment, at the Otago Museum and University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (October 31).

Demonstrator (some experience essential and preferably with L.I.M. qualification) in the Materials and Metallurgy Section, to assist in the supervision of laboratories for metallography, heat treatment and testing of steels and light alloys—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks.

Demonstrator in Pharmacy—The Registrar, The University, Nottingham.

Lecturer or Assistant Lecturer in Psychology, to be responsible for the course in physiological psychology—The Registrar, The University, Hull

Lecturers and Assistant Lecturers in Engineering in the Departments of Civil, Mechanical, Electrical and Mining Engineering—The Registrar, The University, Nottingham.

Mathematician (male or female, with a university degree and preferably with some experience in statistics) to assist with a programme of research in the field of naval architecture—The British Shipbuilding Research Association, 5 Chesterfield Gardens, Curzon Street, London, W.1.

Physicist/Metallurgist (with a good engineering or science degree, or equivalent qualification) in the Materials and Metallurgy Section, to lead a research project on the fatigue properties of light alloys—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks.

Research Assistant (preferably with a good engineering qualification and some laboratory and workshop experience) in the Materials and Metallurgy Section, for work associated with the fatigue of light alloys—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks.

Scientific Officer (with an honours degree in physics or mathematics, preferably with postgraduate course in meteorology and at least one year's postgraduate experience) at the Royal Observatory, Hong Kong, for general scientific duties, including independent forecasting—Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD 57/51/03.

Senior Lecturer in Animal Husbandry at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

Senior Lecturer (with M.Sc. degree, at least five years experience of teaching and laboratory work in a British university, also with experience of high voltage practice) in Electrical Engineering, at the University of Rangoon, Burma, to teach electrical engineering up to degree standard, also to set up high voltage and electric machines laboratories—The Ministry of Labour and National Service (H.9), Almack House, King Street, London, S.W.1, quoting A.12/BUR/TOS/36.

Senior Research Assistant (with postgraduate experience in the mechanics of solids, particularly elasticity) in the Department of Mining Engineering, to work on the theoretical analysis of ground movements in mining, under the supervision of the Professor of Applied Mathematics—The Registrar, The University, Nottingham

Dixon Gauze Rings

HIGH EFFICIENCY PACKING FOR LABORATORY FRACTIONATING COLUMNS

S22-950 Dixon Gauze Rings, stainless steel, $\frac{1}{16} \times \frac{1}{16}$ in. 100 mesh
Approximately 110,000 per litre
S22-955 $\frac{1}{8} \times \frac{1}{8}$ in. 100 mesh
Approximately 23,000 per litre
S22-960 $\frac{1}{4} \times \frac{1}{4}$ in. 60 mesh
Approximately 3,000 per litre

Dixon Gauze Rings combine advantages of the regularly arranged gauze packings with those of the random packings. The packing density and effective area of gauze are high. The H.E.T.P. is small even for large boil-up rates; the hold-up per theoretical plate is small, and the packing can be used satisfactorily under reduced pressure.

Three ring sizes are available, the largest being intended for large-scale applications in which high through-puts are of more importance than large plateage. The smaller rings are intended for work in which the greatest plateage is needed at the lowest cost.

Please write for further information.

RESEARCH FACILITIES

Session opens September 23, 1957, Final Enrolment: September 16 to 19, 1957: 10 a.m. to 12 noon, 2 p.m. to 4 p.m. for day students; 6.30 p.m. to 8.30 p.m. for evening students.

Full-time and Sandwich Course students should apply at once.

C. E. GURR, M.Sc., Ph.D.,
Secretary to the Education Committee

CHELSEA POLYTECHNIC

(College of Advanced Technology)
DEPARTMENT OF PHYSICS

Session 1957–58: Postgraduate Evening Courses begin September 23, 1957. Subjects available: Acoustics and Vibration Physics; Nuclear Physics, Optics; Physical Electronics; Quantum Mechanics; Semiconductors; Electro-magnetism. Ancillary Courses include Electronic Circuit Theory. Enrolment: Tuesday, September 17, and Wednesday, September 18, 6–8 p.m.

Further details and application forms from the Secretary, Physics Dept., Chelsea Polytechnic, Manresa Road, S.W.3. FLAxman 5747.

COLLEGE OF TECHNOLOGY

BIRMINGHAM
(COLLEGE OF ADVANCED TECHNOLOGY)
DEPARTMENT OF PHYSICS

Full and Part-time Courses are offered for the B.Sc. general and special degrees in physics of the University of London and Part-time Courses for national certificates in applied physics and graduateship of the Institute of Physics. A four-year Sandwich Course in applied physics leading to Associateship of the College and the Diploma in Technology, and giving exemption from the graduateship examination of the Institute is also offered. Students are also accepted for research leading to London M.Sc. and Ph.D. degrees.

Applications to the Registrar, College of Technology, Suffolk Street, Birmingham, 1.

RADIOISOTOPES, THEIR MEASUREMENT AND USES

The next full-time course of four weeks' duration on the use and measurement of radioisotopes will be held in the Department of Chemistry,

SIR JOHN CASS COLLEGE
JEWRY STREET, LONDON, E.C.3

beginning on Monday, October 14, 1957.

The course will be largely practical in content and will be suitable for those of graduate standing. Places are strictly limited. Fee: £30.

Further particulars and application forms may be obtained from the Secretary at the College.

Further courses will be held beginning on Monday, January 27, 1958, and Monday, May 12, 1958.

NORTHERN POLYTECHNIC

HOLLOWAY ROAD, LONDON, N.7
A COURSE OF TWELVE LECTURES ON
GAS CHROMATOGRAPHY

will be given on Tuesdays from 6.30 to 8.30 p.m. beginning Tuesday, October 22, 1957

Lecturers: Mr. R. P. W. Scott (Benzole Producers Ltd.), Dr. D. Ambrose (Chemical Research Laboratory, D.S.I.R.), Mr. D. H. Desty (The British Petroleum Co., Ltd.)

Syllabus includes—principles involved, detectors, ancillary equipment, analysis techniques, theoretical aspects, industrial applications, large-scale equipment. Practical demonstrations with apparatus provided by leading firms.

Fee: 21s. Enrolment limited.

Apply now (enclosing fee) to Dr. W. Gerrard

CITY OF LIVERPOOL EDUCATION COMMITTEE

CITY COLLEGE OF TECHNOLOGY
DEPARTMENT OF CHEMISTRY AND BIOLOGY
COURSES IN PRACTICAL RADIOCHEMISTRY

A number of full-time Courses on Practical Radiochemistry will be held at this College beginning in November, 1957. Each Course will last two weeks and will include lectures and demonstrations as well as practical work.

Full particulars and enrolment forms may be obtained from the Head of the Department of Chemistry and Biology, College of Technology, Byrom Street, Liverpool, 3.

THOMAS ALKER,
Town Clerk and Clerk to the
Local Education Authority.

(J.4911)

OFFICIAL APPOINTMENTS

UNIVERSITÉ DE MONTREAL

DÉPARTEMENT DE PHYSIQUE
MONTRÉAL, CANADA
ATTACHÉ DE RECHERCHES

The Attaché de recherches will be invited to join the 500-kilovolt accelerator-group, to participate in the present work on fast neutrons and, if he so desires, to initiate other research work. Teaching duties can be arranged if desired, but a speaking knowledge of French would then be required. Candidates should preferably have a Ph.D. degree in physics and have some experience in the field of nuclear physics, either theoretical or experimental. The initial salary will be approximately in the range of $5,000 to $6,000 per annum, plus an allowance towards travelling expenses. This post is available immediately.

Applications should include a curriculum vitae and the names of two physicists as referees. They should be addressed to the Directeur, Département de Physique, Université de Montréal, Case Postale 6128, Montréal 2, Canada.

UNIVERSITÉ DE MONTREAL

DÉPARTEMENT DE PHYSIQUE
MONTRÉAL, CANADA
THREE TEACHING POSTS AVAILABLE

Applications are invited for three teaching posts ranging up to that of Professeur titulaire and involving both research and teaching. A speaking knowledge of French is required. The Département de Physique is presently active in the following fields: inelastic scattering of fast neutrons, nuclear emulsions, cosmic rays and electron diffraction in gases. Both theoretical and experimental physicists interested either in these or other fields are invited to apply. Research facilities are good. Salary and title will be commensurate with experience, and an allowance will be made towards travelling expenses. The University provides free life insurance and a retirement plan. These posts are available immediately.

Applications should include a curriculum vitae and the names of two physicists as referees, and should specify the salary required. They should be addressed to the Directeur, Département de Physique Université de Montréal, Case Postale 6128, Montréal 2, Canada.

UNIVERSITY OF BRISTOL

Applications are invited for the appointment of Lecturer (Grade I or II) in Low Temperature Physics. Grade and salary according to qualifications. The vacancy arises from the impending resignation of Dr. L. C. Jackson. Salary scales: Grade I, £1,550 by £75 to £1,925; Grade II, £900 by £50 to £1,350 by £75 to £1,650. The Lecturer will be required to give instruction in Physics and to lead the Low Temperature Research Group under the direction of the Professor of Physics.

Applications should be sent to the Registrar, The University, Bristol, 8, from whom further particulars of the post may be obtained, by October 1, 1957.

UNIVERSITY OF QUEENSLAND

AUSTRALIA

Applications are invited for the position of Lecturer in Mathematics within the Department of External Studies. Applicants should possess an honours degree in mathematics. Salary £A 1,300 to £A 1,750 per annum.

Further particulars and information as to the method of application may be obtained from the Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1. The closing date for the receipt of applications, in Australia and London, is October 18, 1957.

GOVERNMENT OF THE FEDERATION OF RHODESIA AND NYASALAND

VACANCY: MEDICAL ENTOMOLOGIST

Applicants should preferably hold at least second-class honours B.Sc. degree with entom logy or zoology as major subjects or a high academic qualification. Commencing salary wi in range £900 to £1,250 according to qualificatio and experience on scale rising to £1,850 annum.

Application forms and further particulars fr the Secretary (R), Rhodesia House, 429 Stran London, W.C.2. Closing date October 12, 19

NATIONAL INSTITUTE OF AGRICULTURAL BOTANY

Applications are invited for the following post

1. Regional Trials Officer, to work at the Coun Institute of Agriculture, Winmarleigh Ha Lancs.
   Salary Scale £770 (age 26 or over) to £1,2 per annum.
2. Assistant Trials Officer, to work at Leeds U versity Farm, Headley Hall, Yorks.
   Salary Scale £545 to £760 per annum.

The increase in Civil Service pay recently a nounced, will be added to the scales quot above. Superannuation under the F.S.S.U.

Degree in botany or agriculture or equivale qualification with practical experience in cr production required.

Application forms and further particulars fro M. G. Tozer, Secretary, N.I.A.B., Huntingd Road, Cambridge.

UNIVERSITY OF BIRMINGHAM

DEPARTMENT OF EXTRA-MURAL STUDIE

Applications are invited for the post of St Tutor in Physical Science. Good qualificatio in any branch of the physical sciences will considered. The post offers special opportuniti for experimental work both in the developme of science teaching to adult groups and in t tutor's own field of research. The tutor will expected to co-operate closely with Departmen of the Faculty of Science, especially those co cerned with his own field. Salary range £900 £1,650 per annum, initial salary according qualifications.

Applications (eight copies), together with name of two referees, should be sent by September 1957, to the Director of Extra-Mural Studie The University, Edmund Street Birmingham, from whom further particulars may be obtaine

MINISTRY OF HOUSING AND LOCA Government. The Civil Service Commissioners vite applications from men for about twelve per sionable posts (a) six District Alkali Inspectors Six Alkali Inspectors under the Alkali Work Regulations Act, 1906. Vacancies at Birmingha Bristol, Cambridge, Cardiff, Leeds, Liverpoo London, Manchester, Newcastle upon Tyne, She field, Stoke-on-Trent. Considerable travelling current regulations provide for first-class rail car mileage allowance plus subsistence allowanc Candidates must be prepared to serve in any cont Duties include the administration of the Alkali et Works Regulation Act, 1906, as extended fro time to time by Orders, to control the emission air of noxious fumes, smoke dust, etc., fro certain industries, to ensure the proper desig layout and operation of plant for this purpo The posts afford scope for initiative and ind vidual responsibility. Inspectors will enjoy co siderable freedom of action within their spher and will be expected to organize their work an to take decisions with the minimum of superv sion. It will be an important part of their dut to establish and maintain good relations with i dustrial managements and local authorities in the areas. Age on August 1, 1957, posts (a) at lea 35; posts (b) at least 30. Candidates must b university graduates in science or technology an wide experience and knowledge of chemical fuel technology and engineering and of related i dustries are essential. Candidates for posts must have had about ten years experience an for posts (b) about five years. London startin salary for posts (a) £1,590 at 35 up to £1,780 38 or over, salary maximum £2,050; and f posts (b) £1,150 at 30 up to £1,280 at 33 or ove salary maximum £1,720. Slightly less for pos outside London. Exceptionally, higher startin pay at 38 (or over) or 33 (or over) respectively outstandingly well qualified. Prospects of pr motion. Five-day week. Five weeks annu leave. Non-contributory retirement pension an gratuity.—Application form and full particula from the Secretary, Civil Service Commissi Scientific Branch, 30 Old Burlington Street, Lo don, W.1, quoting No. S 4748/57. Applicatio to be returned by September 30, 1957.

INFORMATION SERVICES IN THE MODERN WORLD

THE White Paper on Overseas Information Services* which has resulted from Dr. Charles Hill's re-examination of those services should go some way to remove any misgivings which have been aroused by the Prime Minister's statement last January, particularly in view of the delay of the Government in taking action on the recommendations of the Drogheda Committee. Dr. Hill's review has not been published, but the recommendations set forth in the White Paper largely follow those of the Drogheda Report, and when effect has been given to the decisions now taken, the estimated cost of the information services will be about £15 million a year, an increase of some £2 million a year. In addition, capital expenditure is envisaged of the order of up to £5·5 million, or slightly more than the figure which Lord Gosforth, speaking for the Government in the House of Lords on February 6, claimed it would cost to implement the recommendations of the Drogheda Committee.

This expansion, it is now admitted, is necessary to maintain British overseas information services at a level consistent with our world-wide responsibilities, and to ensure the necessary reinforcement of our national policies and our associations in the defence of the free world. This expansion, however, is concerned essentially with the structure of those services, and the White Paper also admits that more needs to be done to ensure that the quality of those services is high, and that problems of staffing and training remain to be examined. Moreover, the official service is only a part of the whole, and more opportunity and encouragement should be provided for people and organizations outside government to assist in developing the full impact of Britain's influence overseas. The necessary administrative arrangements, ministerial and official, to deal with these problems on a regular basis and continuously to co-ordinate the overseas information services have already been made, and there is no intention to establish a Ministry of Information, nor will there be any encroachment on the responsibility of individual Ministers for the work of their information staffs.

This realistic decision to spend more money on what is to-day an essential instrument of policy is welcome also for the clear evidence it gives that the Government recognizes that information services are one of the means by which policy is promoted and opinion influenced, and that their effectiveness depends not only on their size and cost but also on their use of modern techniques. The costs of those techniques are steadily rising, and for that reason alone, although the expansion on which the Government has now decided will cost rather more than that recommended three years ago in the Drogheda Report, its magnitude in terms of effort will be well below that regarded as necessary by the Drogheda Committee; nor indeed has the Government accepted all the curtailments recommended by that Committee. The French, Italian, Danish, Dutch, Norwegian, Swedish and Portuguese services are not all to be abolished, although economies are to be made offering a saving of some £200,000 a year, including the abolition of the last five services.

This decision is for reasons of policy, to which information effort must obviously be geared. The closing of the transmitting stations involved in complete abolition would weaken the transmissions across the Iron Curtain, and might undermine confidence in our continuing interest in Western Europe. Apart from this, however, expansions in the external services of the British Broadcasting Corporation, estimated to add £258,000 to the present annual cost of nearly £5·75 millions, have been approved. In addition, much of the Corporation's equipment needs replacement or modernizing, and the Government has approved in principle a programme of capital replacement, the phasing of which is to be discussed with the Corporation. Furthermore, in affirming that the Corporation enjoys independence of programme content, the White Paper also states that, in the Government's view, the impartiality and objectivity of the British Broadcasting Corporation are national assets of great value, and that the Corporation's independence should be maintained. Independence can be consistent with a close liaison between overseas departments and the Corporation on the basis of mutual confidence and understanding, and it may be concluded that Dr. Hill has done something to promote departmental accord and understanding.

While in many countries sound will remain the main broadcasting medium for the immediate future, the White Paper recognizes that British information services must take full advantage of the opportunities which television offers. While it is too early to define a hard-and-fast policy, the Government has decided on some immediate expansion of television activities. In so far as the various agencies concerned with the promotion of television overseas, including the British Broadcasting Corporation, can secure the export of their air material, they are warmly encouraged to do so. Where they produce for home consumption material which the Foreign Office, the Commonwealth Relations Office, the Colonial Office or the Board of Trade thinks it would be useful to have exhibited overseas, although commercial showing would be unremunerative, the Central Office of Information will be authorized to negotiate for the rights in that material for the area concerned, while the Central Office of Information will substantially extend its activity and expenditure in the development of television films. It proposes to offer about an hour a week of British material to the principal stations in most countries where television operates, other than those behind the Iron Curtain, including a weekly news service for Colonial use; and there will be more Commonwealth 'televiews' for Australia and Canada and new series of programmes in foreign languages. It will also supply to selected posts overseas libraries of background shots of material about Britain for use in television programmes.

---

* Overseas Information Services. Pp. 8. (Cmnd. 225.) (London: H.M. Stationery Office, 1957.) 6d. net.

Careful study of the work of the British Council, which, although it has political and commercial effects in the broadest sense, is confined to the educational, scientific, professional and cultural fields, appears at last to have convinced the Government both of the high quality of material which the Council produces, and the value of its work in fostering contacts with influential individuals, particularly in the professional classes, and with students who are likely to be leaders of opinion in their own countries. High importance is now attached to its care of students who come to Britain from the Commonwealth and from foreign countries, and to its furtherance of the teaching of English; and besides certain extensions to the Council's overseas posts, the Government has decided on urgent expansion of the teaching of English, the demand for which already greatly exceeds the supply.

The White Paper points out that the English language is a commodity in great demand all over the world. It is a key to our literature and so to our culture, quite apart from the fact that it has largely replaced French and Latin as an international language. It is thus a valuable export likely to facilitate the export of British advisers and technologists, British technological and university education and British plant and equipment. The advantages to be gained from increasing the number of potential customers who can read technical and trade publicity material written in English are obvious.

The main factors deterring United Kingdom teachers of English from taking posts overseas, other than in the Colonies, are lack of assurance about adequate salary and security of contract and uncertainty of re-employment in Britain on return. These difficulties can sometimes be met by extending the practice of giving a teacher going abroad a contract with the British Council, which would accept responsibility for filling the post on behalf of an overseas authority; but it may also at times be necessary for the British Council to give financial assistance if the overseas post is to be attractive to teachers from Britain, and accordingly the Ministry of Education and the Scottish Office will establish an agency to assist both the Colonial Office and the British Council in recruiting teachers for overseas posts, including teachers of subjects other than the English language. This agency will also assist reinstatement on a teacher's return. Up to one hundred scholarships will be established to enable key students from overseas to come to Britain for training in teaching the English language, and the British Broadcasting Corporation is being requested both to expand its "English by Radio" programmes and to consider including more such material in other programmes.

Other forms of expansion in the British Council's central services on which the Government has decided include, besides increases of staff, an improved pension scheme, the extension of the Council's programme for the care of visitors, especially from the Commonwealth and the Middle East, and increased grants for the inter-university exchange scheme and student welfare services, and more British Council books and periodicals for libraries. Here we touch on a factor to which neither the White Paper nor the Drogheda Report appears to attach sufficient weight. The latter accepted the view that libraries of English books are the essential core of all British Council centres abroad, and noted the observation of the Foreign Office that in various countries the import of British books is impeded by exchange restrictions. It also recognized the importance of the Press as a vehicle of information; but it failed to emphasize the great part which periodicals and books have to play in making known the British way of life and the British contribution to human thought and achievement.

The Foreign Office suggested that for countries where exchange difficulties arise, a scheme such as the British Book Export Scheme, which worked well in the years immediately following 1945, should be adopted. Under this scheme the British Government paid the British exporter, while the foreign importer made payment in his own currency, either to the British diplomatic mission or into a blocked account from which periodic releases were made, or both. Something of this nature would still appear to be required, for it is principally in such countries as Turkey, Indonesia, South America, India and Pakistan, where Dr. Hill's survey has indicated that an extension of information about Britain is needed, that sterling is short, and libraries, universities and individuals are unable to purchase the British books and periodicals they need and desire. Moreover, the position is made worse by the subsidies by which the United States ensures that American text-books and periodicals are at the disposal of a world hungry for information conveyed in the English language.

As a concrete example Turkey may be cited; the import of British books and periodicals in Turkey was stopped in 1955 because of a currency crisis. To-day they appear to be scarcely obtainable in Turkish bookshops, whereas French and German books are fairly easily procurable and American publications occupy the position formerly held by British publications. This matter is, of course, rather outside the range of Dr. Hill's recent inquiry, but it bears too closely on the effective functioning of information work for complacency at the Board of Trade about the relative positions of exporters of British books and periodicals and their American counterparts, which has recently been the subject of strong complaints. Much of the benefit of the expansion of the teaching of English overseas will be lost if British books and periodicals are not available for new potential readers.

Nor is currency the sole difficulty which handicaps the export of British books and periodicals. Recent steep increases in postage and mounting costs of paper and printing have jeopardized the existence of various learned periodicals in Britain. Further increases in the price of those that survive are almost inevitable, and this will make it still more difficult for the foreign reader to buy British scientific and technical periodicals and books—literature which has in the past made no small contribution to Britain's prestige in the world.

The difficulties under which the distribution of British scientific and technical literature in the world labours to-day are too much the direct or indirect result of official policy for a Government to be indifferent; especially when that Government has affirmed so unequivocally as in Dr. Hill's White Paper its belief in the value of overseas information services, both official or unofficial. In large measure, the difficulties can only be removed by Government action, though it should not be forgotten that information services can only extend Britain's influence and prestige in the world if there is a worthy way of life and great achievements to project. There should be no complacency in that respect, as the events of this year have shown. Nevertheless, the learned societies and professional associations might well consider some fresh approach to the Government, possibly through the medium of the Parliamentary and Scientific Committee, on this broad issue of the future of British scientific and technical periodicals and books, and how they can once again be enabled to make their full and proper contribution to British prestige in the world.

There is much which is welcome in the White Paper on Overseas Information Services, particularly the recognition of the opportunities which television affords and of the importance both of continuity and of other and independent means of influencing public opinion; nevertheless, vigilance and much effort on the part of independent bodies will still be required. Even now the best assurance that continuity will be maintained in the official services probably lies in an all-party approach to the whole question, particularly if the impending changes in the sound programmes of the British Broadcasting Corporation are not to impair our resources. Moreover, such an approach would make its own contribution to ensuring that there is a worthy picture to present. Nor can it be too often emphasized that it is only by the assiduous efforts of independent bodies that the most effective use can be made even of the official information services. By and large, it is through the vigilance of such bodies that mistakes are rectified and obstacles to the presentation of British achievements and ideas are removed, whether in broadcasting, in the Press or in any other ways. It is only when such independent bodies take their full share of the presentation of the life and work of Britain that the full effect of the British Broadcasting Corporation's high reputation for objective and honest reporting will be felt. What matters is not that there should be one voice of Britain, but that the many voices and means which set forth British ideas and policy and achievement should be inspired by a like ideal, and tell their story—forcefully if need be—but objectively and clearly.

RELIGION AND HUMANISM

Religion without Revelation

By Dr. Julian Huxley. New and revised edition. Pp. xii+252. (London: Max Parrish and Co., Ltd., 1957.) 21s. net.

"WHAT the world needs is an essentially religious idea system" (including "beliefs, attitudes and general assumptions as well as intellectual ideas"), but it must be an idea-system which has come to terms with the methods and results of the sciences of Nature and man. That means that it must be a religion without revelation and without belief in a personal God. Such is the challenging and thought-provoking thesis propounded by Dr. Huxley in this work, which was first published nearly thirty years ago and now appears in a new edition with alterations and additions but with its main conclusions still the same.

Dr. Huxley writes as a distinguished scientist who has been profoundly interested in and influenced by religion from his early years. He has an extensive knowledge of the relevant literature. His evidence is drawn from personal experience, as well as from anthropology, comparative religion and religious psychology, and he writes with complete candour. Whether or not they agree with his assumptions, his arguments and his conclusions, scientists and theologians and reflective members of the general public who would like to be able to give a reason for the faith that is in them should find his treatment stimulating and suggestive. Dr. Huxley's objection to revelation is that "in any straightforward sense of the term" it is inconsistent with the method of science, according to which "truth is not revealed once for all, but has to be progressively discovered". Belief in an infallible God-given revelation, he contends, dispenses men from further inquiry, leads to fanaticism and is a bar to progress. Moreover, he thinks, there is no God, no personal or supra-personal supernatural agent from whom the revelation could come. Science has been gradually showing that the phenomena which were once regarded as due to the activities of supernatural agents are in fact the results of the operation of natural causes. The belief in the existence of such agents "is best thought of as in origin a natural and inevitable error of primitive thinking . . . a mistaken projection of personality into the non-personal", which "it will soon be as impossible for an intelligent educated man or woman to believe in as it is now to believe that the earth is flat or . . . that death is always due to witchcraft".

That is the negative aspect of his thesis. The positive aspect is that religion is important and necessary, as necessary as science and as firmly based on experience. If we say that religion is an experience, and theology a theoretical interpretation of that experience, we might state Dr. Huxley's view as being that there is no conflict between science and religion, but that there is a conflict between science and certain theologies. Those theologies are hypotheses to explain the facts which give rise to religious experience, but the progress of science has shown them to be erroneous. The facts and experiences themselves, however, are real and important. Dr. Huxley's account of them, however, is neither clear nor consistent. Certain situations or occurrences which have or are believed to have a bearing on human destiny give rise to what he sometimes calls 'a feeling', sometimes 'a feeling and belief', sometimes 'a sense', and sometimes 'an apprehension' of sacredness or holiness or sanctity. This variety of expressions betrays a wavering between two inconsistent views, both of which would seem to be necessary to his thesis. According to one, the main and certainly the original element in religion is feeling or emotion, and this feeling tends to find expression in ritual practices, and gives rise to certain beliefs. According to the other, the experience is from the first cognitive, the awareness or apprehension of 'a sacred reality' which gives rise to a feeling of reverence or awe. But what Dr. Huxley wants specially to emphasize is that the situations, the feelings, the beliefs and the actions concerned are all natural, all situations or events either in external Nature or in the history of the human mind. There is, in fact, no supernatural event or agent, no higher being than man, no source for his ideals and values except his own nature.

The negative aspect of Dr. Huxley's thesis is more definite and precise, and the case in support of it is more consistently and forcefully argued. The positive aspect, to which he would seem to attach at least equal importance, is less clearly and consistently developed. On this side what we seem to find is less the systematic development of an argument than a series of essays on specific topics, written at different times and for different purposes, and united only by their opposition to revelation and the idea of God. The account of the theology or world-view which he would substitute for them seems to vary from context to context. For example, when Dr. Huxley is arguing that his view retains all that is essential to religion, he emphasizes the mysterious, awe-inspiring, 'sacred reality' which we find in religious experience; but when he is expounding evolutionary humanism, 'the religion of the future', the emphasis is on human ideals and values naturalistically conceived, and on man as the creator of his own values, the master of his destiny and the director of evolution. No reference is made to and no room seems to be left for a sense of a sacred reality which alone would seem to provide an object worthy of worship. Accordingly, though there is much in the work that is true and wise and penetrating, its main argument seems to me neither convincing nor consistent; and if its main conclusions were established, I think it would be more in keeping with linguistic usage to call the result an ethical system than a religion.

A. MACBEATH

THEORY AND TECHNOLOGY OF SEMICONDUCTORS

Semiconductors

Their Theory and Practice. By Prof. G. Goudet and C. Meuleau. (Translated by G. King.) Pp. xviii + 316. (London: Macdonald and Evans, Ltd., 1957.) 105*s*.

Rectifying Semi-Conductor Contacts

By H. K. Henisch. (The International Series of Monographs on Physics.) Pp. xii + 372. (Oxford: Clarendon Press; London: Oxford University Press, 1957.) 70*s*. net.

PROF. G. Goudet and C. Meuleau have attempted to give a comprehensive summary of the present state of semiconductor theory and technology. This is an enormous task in a single volume, and it is inevitable that certain aspects of the subject cannot be treated as fully as one would wish. Here the emphasis has been placed more on the basic theoretical ideas than on the experimental aspect of semiconductors, with the result that in some of the later parts of the book dealing with experimental work, the information given is incomplete, and in some cases rather misleading. For example, in discussing measurements of minority carrier life-time, the authors spend considerable space on the Valdes method of measurement, when in fact the photoconductive decay method, which is mentioned only briefly, is nowadays generally preferred, especially in the case of silicon.

The book is divided into three parts. In Part 1, the development of semiconductor theory is traced on the wave mechanical basis of de Broglie and Schrödinger; some discussion is also given of the statistical mechanics of particle behaviour leading to the Fermi–Dirac statistics, and the band theory of electronic energy distribution in solids is outlined. The authors then proceed to examine the mechanism of charge movement in semiconductors, treating in detail the effects of electric and magnetic fields on the movement of charge carriers and introducing such important parameters as mobility, diffusion constant, and minority carrier life-time.

In Part 2, which is concerned with the technology of semiconductors, the influence of crystalline perfection on the electrical properties of the more important materials is considered. In much of this section, the information presented is too brief to be of real value to the worker in the field of semiconductors, this being particularly true of Chapters 6 and 7; for example, in Chapter 7 only a brief outline of the methods of crystal preparation is given, and the bibliography appears rather limited for a book of this type.

Part 3 concerns the principal applications of semiconductors and covers in some detail crystal diodes and rectifiers, transistors and photocells. Here the aim has been to compare the various types of device rather than to give a detailed description of each. Considerable space is devoted to point-contact and grown-junction transistors, and it may be that more emphasis should have been placed on the alloyed- and diffused-junction types in view of the developments of the past few years.

On the whole, this book should be a good theoretical reference work for the worker engaged in semiconductor activities, and provide also a useful introduction to semiconductor technology for those entering this field.

Mr. G. King, who is responsible for the translation from the original French, has produced a most readable text.

Dr. H. K. Henisch provides a survey of the present state of knowledge of contact phenomena and rectification at semiconductor surfaces. This book is a welcome addition to the literature on semiconductors; in the present state of semiconductor development, it is probably true to say that the phenomena occurring at semiconductor surfaces are the least understood part of the subject, and in this volume Dr. Henisch has collected a basic fund of knowledge upon which any investigator of surface and contact phenomena may usefully draw.

The book begins with an introductory section devoted to the theory of electrons in solids, which is followed by a chapter describing the bulk properties of germanium, silicon, lead sulphide, selenium, and cuprous oxide. Practical forms of metal–semiconductor rectifiers, of both the large-area and point-contact types, which use these materials, are discussed in detail, and three chapters are then devoted to an examination of the various theories of rectifying contacts which have been proposed.

The final chapters contain a most useful description of important experiments on point-contact and area-contacts between metals and semiconductors, and an interpretation of the experimental results is given in each case. Dr. Henisch is particularly well qualified to describe this work, since important contributions to it were made by him and his co-workers in the University of Reading.

Although in the past few years the emphasis has been largely transferred from surface-rectifying barriers to *p–n* junctions, the problems of surface physics associated with such junctions are very closely allied to those of the surface-rectifying barrier, and for this reason, the material contained in this book will be of use to all those concerned with the theory and applications of semiconductors.

TECHNIQUE IN ORGANIC CHEMISTRY

Technique of Organic Chemistry

Edited by Arnold Weissberger. Vol. 3. Second completely revised and augmented edition. Part 1: Separation and Purification. Pp. xi+873. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1956.) 17.50 dollars.

A Guide to Qualitative Organic Chemical Analysis

By Prof. R. P. Linstead and Dr. B. C. L. Weedon. Pp. xi+169. (London: Butterworths Scientific Publications; New York: Academic Press, Inc., 1956.) 21*s*.

Semimicro Qualitative Organic Analysis

The Systematic Identification of Organic Compounds. By Prof. Nicholas D. Cheronis and Prof. John B. Entrikin. Second edition. Pp. xiv+774. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 9 dollars.

Organic Analysis

Vol. 3. Editorial Board: John Mitchell, Jr.; I. M. Kolthoff; E. S. Proskauer; and A. Weissberger. Pp. viii+546. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1956.) 11.50 dollars.

When Faraday condensed his knowledge and experience of laboratory practice into one volume of about six hundred pages, he could not have foreseen the developments in practical chemistry that would eventually require a shelf full of books to describe the technique necessary for any one of its specialized branches. Yet the application of more and more new methods to the elucidation of problems of chemical structure or of reaction mechanism makes it essential for the practising chemist to have information on these matters in an accessible and collected form. For the organic chemist this has been done in a series of nine volumes under the general title "Technique of Organic Chemistry" edited by A. Weissberger. The worth of the collection can be measured by the tattered condition of library copies and by the fact that new editions of these volumes are being issued. One of these, Vol. 3, is split into two parts, of which the first is a subject of this review. It deals with the separation and purification of organic compounds by crystallization, filtration, extraction and diffusion methods. There are also chapters on solvent removal and centrifuging. These accounts are up to date, authoritative and plentifully supplied with references to original papers and other sources of information. Yet when they deal with general descriptions of techniques which have been practised since the beginning of chemistry they give the impression of being somewhat too diffuse. There is a stimulating section of the chapter on diffusion methods, which discusses the application of thermal diffusion for the separation of liquid mixtures. The technique of this method is still being developed and it offers the prospect of a useful means of separating some pairs of liquids of approximately the same boiling point.

In spite of the increasing number of new techniques which are being used by organic chemists, instruction in the art of qualitative organic chemistry is still an essential part of the training of a chemist. It provides the student with the opportunity of linking deduction to observation and of acquiring at first hand some experience of the exercise of independent judgment and the selection of suitable methods for testing his conclusions. Qualitative organic analysis is indeed essential to any complete course in organic chemistry; its value to the student is determined almost entirely by the way the subject is presented. It is of more than usual interest to all who are charged with the instruction of students in practical organic chemistry to have available, in book form, the system of instruction which has been developed in the Chemistry Department of the Imperial College of Science and Technology. In this book, "A Guide to Qualitative Organic Chemical Analysis", by Drs. Linstead and Weedon, is outlined a scheme for the identification of single substances based on the reactions of the functional groups and their characterization by the preparation of suitable derivatives. There are twenty-seven tables giving melting and boiling points of the commoner members of typical groups of organic compounds and their derivatives. Clear directions are given for the preparation of characteristic derivatives of each group. There is also a short chapter on the examination of mixtures. The book is written for students taking an honours degree in chemistry; it also provides a sound and satisfactory basis for more advanced work. It can be recommended to the attention of all who teach practical organic chemistry and it should be in the possession of all students reading for a degree in chemistry.

The first edition of "Semimicro Qualitative Organic Analysis" by Profs. Cheronis and Entrikin was published in 1947 as a relatively slender volume of about five hundred pages; this new edition has been expanded by about 250 pages by adding to the existing material and by introducing new sections. The subject-matter has also undergone some reorganization. The emphasis of the book is on manipulation of semimicro quantities and its chief merit is in the descriptions it gives of the preparation of derivatives for the characterization of functional groups. There are also very complete tables of physical constants to aid the identification of organic compounds as well as schemes for the recognition of typical groups. These sections are preceded by an account, about 150 pages in length, of techniques for handling small quantities of material. Operations such as crystallization, distillation, extraction and chromatographic separation are described in considerable detail and there are some useful descriptions and diagrams of suitable apparatus. A small section on infra-red absorption spectra is also included.

From the authors' introduction, it appears that the book is designed to be used not only by practising organic chemists but also by students who are starting practical organic chemistry. In this, it is possible that the authors have gone too far in their enthusiasm, for it is extremely doubtful if any beginner can efficiently acquire a competent technique in the handling of semimicro amounts, without having previously undergone the discipline of well-founded instruction in the art of crystallizing, distilling and purifying larger amounts.

The intention of the editors of the series of volumes under the title of "Organic Analysis" is stated to be to present an up-to-date picture of techniques for the estimation of organic compounds, and reliable and critical information about new methods and procedures. This is a high standard to maintain over a series of volumes, but it is evident that Vol. 3 in no way falls below the standard set by the previous volumes. The general content of Vol. 3 may be gauged from the titles of the reviews; determinations of organic acids, of acid anhydrides, of amines and amides, and of olefinic unsaturation. The volume is completed by a review of the applications of analytical mass spectrometry to organic analysis, and by one on the analytical characterization and determination of some commercially important classes of synthetic organic coating resins. These reviews are of special interest to the analyst, but can be read and used with profit by organic chemists with more general interests. In particular there is a satisfying and critical survey of methods of estimating unsaturated linkages; it covers not only methods based on saturation of the double bond, but also those depending on what the authors call 'instrumental methods', among which are infra-red and ultra-violet absorption, and chromatographic methods.

W. J. Hickinbottom

SCIENCE AND THE UNITED STATES GOVERNMENT

Science in the Federal Government

A History of Policies and Activities to 1940. By A. Hunter Dupree. Pp. xi+460. (Cambridge, Mass.: The Belknap Press of Harvard University Press, 1957.) 7.50 dollars.

In this book Mr. A. H. Dupree gives a readable and scholarly account of the relations between the Government of the United States and scientific work during the first hundred and fifty years of the Federal Union. It is a picture of the place which science has taken in the growth of the American nation and, concerned rather with the organization of both science and government and the formulation of policy than with the advance of science itself or with technical invention, it makes an admirable complement to Prof. J. W. Oliver's recent "History of American Technology" (see *Nature*, 179, 338; 1957). The development of the Smithsonian Institution, the American Philosophical Society in Philadelphia, the National Academy of Sciences, and the later Carnegie Institution of Washington, the Rockefeller Foundation as well as the Tennessee Valley Authority and the Office of Scientific Research and Development and other bodies created to meet the needs of the country in the Second World War are all seen to fall into their natural places. Mr. Dupree's leisurely narrative provides a background which explains points that sometimes puzzle those overseas regarding the antecedents of that series of reports, following on "Research: A National Resource" and continuing with "Science: the Endless Frontier" and "Science and Public Policy", which emphasized the profound concern of the United States Government to-day with the function and use of science.

The book is, however, something much more than a complement to these reports or to the recent description of the present organization of the Federal Government for scientific activities which the National Science Foundation has published. Mr. Dupree rarely discusses developments, such as Mr. D. K. Price discusses in "Government and Science". He is content to record the facts in such guise that the situation comes alive, and for this reason his book will be of wide interest outside the United States. Essays which display so penetratingly the reactions between science and government are all too rare, and although Mr. Dupree's canvas is ample, this account of the American scene is calculated to assist the understanding of the British scene also, and not least to convey more than a hint to the British scientist on how to handle such relations.

There is indeed nothing that really approaches this book in covering the relations between science and government in Britain over the same period. Prof. Armytage gave some sidelights in "Civic Universities", but no book on the Civil service has covered this aspect, and Dr. D. L. S. Cardwell's recent study of the organization of science in England also passes it over, though it was noticed in some of the studies stimulated by the Perkin centenary last year. It will surprise many to learn from Mr. Dupree's book how long the history of science in America is, how deep the roots of science go both into science and government, and from what early days the United States Government has been concerned to foster science. Well produced as well as written, with ample bibliographical references, and a chronology as well as an adequate index, it will interest all those concerned with the relations between science and government. For a book which illumines those complex relations and their dangers, there are two curious omissions. There is no mention of either the American Association for the Advancement of Science, although *Science* is freely quoted, nor of de Tocqueville, though de Tocqueville's remarks on the influences of democracy upon science in America, and his observations that the democratic principle does not induce men to cultivate science for its own sake and on the neglect of theoretical and abstract knowledge in the United States, are highly relevant to Mr. Dupree's account and endorse his concluding argument.

R. Brightman

The Encyclopedia of Chemistry

Edited by Prof. George L. Clark and Gessner G. Hawley. Pp. xvi+1037. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1957.) 156s. net.

THIS useful volume contains a very large amount of up-to-date material which it would be difficult to find elsewhere in such moderate compass. The articles are written by specialists and are, in general, very good. A wide field is covered and industrial applications receive careful treatment. The volume should be available in reference libraries. Since the book will no doubt go through many editions, it will not be out of place to refer briefly to what the reviewer thinks shortcomings. The index is most inadequate. The editors say that they kept the contributions strictly within the compass planned, and in some cases they have unduly cut down excellent articles and given far more space to poor ones than they deserved. In the accounts of persons and institutions the choice seems to be haphazard; although quite minor American institutions have long sections giving the names of present staff in full, the National Physical Laboratory and other famous foundations are not mentioned. Ostwald is mentioned but not Nernst, Herty but not Harden. Rutherford is still Sir Ernest and Aston is missing. In general, the editors do not seem to have been equal to their task. The spelling is sometimes weak; whether 'van der Waal', for example, is the responsibility of the author or is an editorial correction I do not know, but it should not appear.

J. R. PARTINGTON

Elementary Practical Organic Chemistry

By Dr. Arthur I. Vogel. Part 1: Small Scale Preparations. Pp. xv+348+xiv. (London and New York: Longmans, Green and Co., Ltd., 1957.) 21s.

THE author has planned a three-volume work of which this is the first part. The book opens with forty pages of theory, followed by a long chapter on experimental technique. Besides dealing with customary purification processes, it contains an account of special small-scale apparatus—mostly modifications of familiar types used in macro-work—which the author has tried out and recommends. By standardizing the size of necks of flasks and the diameter of side-arms he has shortened the time required to set up an experiment. These devices and modifications have been carried out in co-operation with a large manufacturing firm, so that the standard apparatus may be obtained through laboratory suppliers. Many teachers will welcome the information in this chapter, for the text is punctuated with helpful notes on theory, comments on reagents and processes, laboratory devices and safety precautions. Chapters 3, 4 and 5 give practical directions for the preparation severally of a selection of aliphatic, aromatic and miscellaneous compounds. Although called 'elementary' these preparations are mostly of the class required by university students. They include one requiring the use of sodium borohydride and one reduction with lithium aluminium hydride. The publishers claim "that the requirements of all examinations involving a knowledge of practical organic preparations are fully met" and that the volume should be suitable for grammar schools, technical colleges and universities. However, it must be pointed out that "elementary organic preparations", so far as British grammar schools are concerned, refer to such compounds as alcohol, acetone, acetic acid, chloroform, ether, ethylene, ethyl acetate and formic acid. The preparation of not one of these is given. Moreover, we are not told whether their omission implies that their preparation on a small scale is not expedient. Dr. A. I. Vogel believes that many of the preparations are new, and he states that all have been checked over in his laboratory. The advice on apparatus and technique, and the experience gone to the making of the book will commend it to teachers. Where it is not used as a class text it should be on the laboratory shelf.

G. FOWLES

Russian-English Glossary of Nuclear Physics and Engineering

Pp. ii+195. (New York: Consultants Bureau, Inc., 1957.) 10 dollars.

THIS excellent compilation gives idiomatic English equivalents of more than 10,000 Russian words and phrases. Its range goes beyond nuclear physics, nuclear engineering and atomic energy to include almost every technical word that might be encountered in Russian literature on those subjects. Errors are very few, and omissions are hard to find. There are some misprints in both Russian and English, but none is likely to cause serious difficulty. The main contribution to the list has been obtained by inverting various English-Russian dictionaries of similar scope, sometimes a little ineptly; it is evident in places that the Russian version is an explanatory translation of the English rather than an expression that might be used in scientific writing.

No grammatical information is included—not even an indication of parts of speech—and common words are not given, so that the glossary is of limited use to anyone not already familiar with Russian. The last page gives the Russian transliterations of various place names connected with work on atomic energy.

The binding is somewhat flimsy for a reference book. The glossary is described as the first of a series, from the same publishers, dealing with various branches of physics and ultimately to be included in "a comprehensive and authoritative dictionary of contemporary Russian terminology in all fields of modern physics". Such a work will be exceedingly valuable if the standard of this first instalment is typical.

J. B. SYKES

The United Kingdom Contribution to the International Geophysical Year, 1957-58

Pp. 72. (London: The Royal Society, 1957.) 10s.

THIS publication provides more than its title would lead one to expect. It contains a short, clear account of each subject to be studied during the International Geophysical Year, covering the observations to be made in each and the problems to be attacked. Each subject is linked with the others. Full details are given of the selection of the special periods, the observations to be made during them, and a calendar of those fixed in advance. Thus far the publication is international in scope, but finally we have also a record of the British share of the work with lists of those British scientists who have planned it. It is a book both to read and keep for reference on details. It is essential for all, professional scientists or laymen, who take a serious interest in the Geophysical Year.

G. A. BULL

JOACHIM JUNG (1587-1657)

By DR. J. H. S. GREEN

THE three hundredth anniversary of the death of Joachim Jung occurs on September 23. The importance in the history of science of his influence and work is not small, and is worthy of notice and summary on this occasion. Jung (Junge, Jungius) was born at Lübeck on October 27, 1587. According to Poggendorff[1] he was for five years from 1609 professor of mathematics at the University of Giessen, but during this early period he also studied pharmacy at Rostock[2]. However, he then moved to Pisa and Padua, graduating in medicine from the latter University in 1618. In view of Jung's later ideas and work this period spent in Italy must be considered of great importance. Singer has written of "that true nurse of the sciences, free Padua", pointing out "that there, alone among the universities, religious tests were so applied as to be in effect, nugatory"[3]. At Padua, some fifteen years after Harvey, Jung came under the influence of the great Fabricius (1537–1619) as continued by his pupil Giulo Casserio (1561–1616) and by Adrian Spigelius (1578–1625). Similarly, at Pisa he was influenced by the tradition of Andrea Cesalpini (1519–1603). Returning to Germany, Jung held a number of appointments: at Rostock and Lubeck as professor of mathematics, with a break of six months at Helmstadt as professor of medicine, and finally at Hamburg where he ultimately became in 1628 rector of the Johannaeum, or high school, until his death in 1657.

Jung's educational activities continued, therefore, for the last thirty years or more of his life. But even as a young man he had been one of a group of educational reformers associated with Ratke (1571–1635). Of particular significance among their activities was the emphasis on the vernacular, for in this respect Germany was especially backward at this time. Jung wrote: ". . . all arts and sciences, as, for example, the art of government, knowledge of weights and measures, of medicine, astronomy, architecture, fortification, can much more easily, comfortably, correctly, perfectly and explicitly be taught and promulgated in German than in Greek, Latin or Arabic"[2]. Notable here is the emphasis on technology. With his versatile activities and enthusiastic advocacy of experimental inquiry, it is not surprising that Jung became involved in controversies with the local priests. He was accused of heresy and threatened with excommunication, though this did not occur. Goethe wrote: "If people had followed the advice of Jungius as to methods of study, the world would have reached, a hundred years earlier, that point at which it is to-day".

The best-known work of Jung is probably that on botany; but he played an important part in two of the most important features of seventeenth-century science—the formation of scientific academies, and the revival of atomism. The Societas Ereunetica was founded by him at Rostock in 1622[2]. Apart from a number of informal gatherings of men interested in science, such as that which gathered around della Porta (1538–1615) in the 1560's, the Societas Ereunetica was preceded only by the Accademia dei Lincei (1600–30), with which Galileo was closely associated in Rome. Jung's society was founded two years before the publication of Bacon's "New Atlantis" but similar influences were at work in the German society, as evidence its motto: *Per inductionem et experimentum omnua*. Jung, like Comenius, was probably influenced by Valentin Andrae's "Reipublicae Christianapolitanae descripto" (1619), which had put forward the idea of an academy similar to that of Bacon. (Andrae has, indeed, been referred to as the Bacon of Germany.) The Societas Ereunetica lasted for no more than two years, and its direct influence was probably small. Though its aim was to carry out experiments, it produced no body of experimental work such as the "Saggi" of the Accademia del Cimento. Its historical significance arises from its early date and from Jung's association with it.

Jung's contributions to the revival of the atomic theory[4] are often overshadowed by those of Gassendi, Sennert, Basso and others; but they are significant and were of contemporary importance. His ideas seem to have been similar to those of Sennert (1572–1637); an account of views appeared in 1619 and more fully in 1636. Jung's views were first written down about 1630 in his "Doxoscopiae Physicae Minores" (published in Hamburg in 1662), but were first published in 1642 in two 'disputations': "Disputationum de principiis corporum naturalium" (March 30, April 2, Hamburg, 1642). These were really academic exercises of the Hamburg gymnasium.

Both Sennert and Jung emphasized that in chemical changes the individuality of the atoms is retained—Jung citing the example of the replacement of copper by iron in a copper sulphate solution. In regarding this as an exchange of atoms and not as a transmutation, Jung was breaking away from the scholastic philosophy, and reverting to the corpuscular theory[5]. Sennert postulated atoms corresponding to each of the four Aristotelian elements, together with elements of the second order (*prima mixa*) formed by a combination of these. Jung conceived his atoms as being of irregular shape, angular and sharp, and in his writings have been seen the ideas of isomerism and stereochemistry.

These views, and those of Gassendi, were known to Boyle, who refers to Sennert in "The Sceptical Chymist" (1661). Sarton has described Jung's (1642) account as "very abstract and forbidding"[6] and states that Boyle is less likely to have known of it than that of Gassendi. It is known, however, that Boyle received a "rude draught of Dr. Jungius' Protonoetical Philosophy" in a letter from Samuel Hartlib in May 1654, though he knew of Gassendi's work earlier than this.

In his botanical work Jung was particularly influenced by the Italian tradition. The botanical garden at Padua, the first to be attached to a university, was laid out in 1545; that at Pisa, provided at the expense of the Medicis, followed two years later. Of great importance was the work of Andrea Cesalpini at Padua, who gave more detailed attention than previously to the morphology of flowers, particularly the organs of pollination, and of Caspar Bauhin (1550–1624), a student of Fabricius, who introduced the binomial system of class names. Cesalpini was strictly Aristotelian in his ideas of the nature of plants, and he retained the traditional four categories of plants—trees, shrubs, half-shrubs and herbs—which he subdivided on the basis of the fruit. Jung took this further in his important developments in classification and morphology; but his considerations were free of Aristotelian speculation.

In describing the various parts of the plant, Jung gave clear definitions, which, although abstract, were the basis of subsequent comparative morphology. Thus, "a leaf is that which stretches out from its place of attachment in height and length so that the surfaces of the third dimension are dissimilar to one another; it is the leaf's inner surface that is differentiated from the outside". On this basis, and the fact that they fell off in autumn, he distinguished compound leaves from the branches with which they were frequently confused. Again, the stem was defined as the upper part of the plant, stretching upwards such that the back, front and sides were indistinguishable, and Jung described the changes of the stem leaves with increasing distance from the ground.

He was unaware of the sexuality of flowers, but described fully the forms of flowers, and on this basis distinguished between the Compositae, Labiatae and Leguminosae families. He rejected the classification into trees, shrubs and herbs, as well as others based on colour, scent, medicinal uses, and so on. Much of his terminology of the parts of plants remains in use to this day, for example, the terms used to distinguish different types of inflorescence. His contributions to morphology and nomenclature were almost the first developments since the time of Theophrastus (372–287 B.C.), and his "Isagoge Phytoscopica" (Handbook of Botanical Study), which was published in Hamburg in 1678, has been referred to as "the most philosophic and scientific treatise on plants that had appeared since the time of Aristotle", and "the foundation upon which the whole superstructure of plant morphology and descriptive botany has been erected"[7].

John Ray (1627–1705) obtained through Hartlib and John Worthington a manuscript of part of this work before 1660 and many of Jung's definitions were incorporated in his "Index Plantarum Agri Cantabrigiensis" (1660) and in later works in which he also acknowledged his debt to Jung and to Cesalpini. Ray's description of the flower is based on the same source. However, Ray retained the traditional divisions on the grounds of expediency, though he agreed that they were popular rather than accurate or scientific. This weakness of Ray's work persisted even after Rivinus (1690) had shown it to be untenable. Indeed, it persisted until the time of Linnaeus (1707–78), who in turn learnt of Jung's morphological principles and terminology from Ray. Linnaeus acknowledged Jung as his precursor in the construction of rules for the description of flowers, and in his descriptions of plant organs was continuing Jung's work.

It is frequently stated that Jung published nothing in his life-time, possibly because his greatest influence was exerted after his death. However, there appeared three editions of his "Geometria Empiria" (Rostock, 1627; Hamburg, 1642, 1649), as well as his "Disputationum de Stoecheosi geometria" (Hamburg, 1634), "Trias quaestionum physicarum de naturalium corporum materia et forma" (Hamburg, 1637), the two disputations mentioned above and other works.

Jung, like Comenius and Harvey, represents a transition period between Aristotelian scholasticism and modern science, and he typifies an early phase of seventeenth century science. His botanical work exemplifies this: he made valuable and enduring contributions by a combination of scholastic logic and accurate observation.

CARBON

THIRD BIENNIAL CONFERENCE

THE third biennial Carbon Conference, sponsored by the University of Buffalo, the U.S. National Science Foundation and the U.S. Office of Naval Research, was held in Buffalo during June 17–21. Interest in the chemical physics of carbon has grown with exceptional rapidity during the past few years. Solid carbon has valuable chemical, mechanical, thermal and electrical properties which indicate various technical uses at ordinary and at high temperatures. The use of highly purified graphite in nuclear reactors provides a second reason for greatly intensified basic and applied research[1]. From a more academic point of view, a close relationship between various properties of the aromatic electrons in condensed aromatic molecules and in graphite has been evident[2] since X-ray structures first became available. However, within recent years a variety of new techniques have been exploited in elucidating the structure and behaviour of graphite and of its crystal compounds. X-ray structural studies have been greatly refined, so as to deal with imperfectly graphitized carbons made from various starting materials. It is generally recognized that such carbons can be regarded as polymers that contain small or large regions of fused aromatic rings, more or less perfectly arranged according to the ideal graphite structure. These regions are joined together in various ways, which can generally be brought nearer the ideal graphite structure by raising the temperature sufficiently so as to expel chemical impurities and reform non-graphitic carbon–carbon bonds. Optical, magnetic and electronic methods of measurement have been pressed into service, and have yielded important new information such as the presence of unpaired electron spins in certain carbons[3]. A wealth of studies on the disruption of graphitic bonds by radiation damage is now being published and forms a new counterpart to earlier lines of investigation on the formation of graphitic bonds by heat treatment. Six papers on radiation damage to graphite were presented at the Conference. There have also been important developments in the mathematical chemistry of aromatic systems, with graphite regarded as the limit of various series of smaller aromatic molecules.

Like the two earlier Carbon Conferences at Buffalo[4], the present Conference was organized by Prof. S. Mrozowski. About three hundred delegates were housed on the campus of the University and were exposed to a very strenuous week of discussions of some eighty papers, a visit to Niagara Falls, and a heat wave. There was no official record of the discussions, which were by common consent stimulating and well sustained, but a booklet of abstracts of the papers has been published by the University of Buffalo. It is planned to embark on publication of the papers presented to the Conference at the beginning of October (probably under the ægis of the University of Buffalo).

Broadly, the Conference was arranged as a succession of papers relating to specific researches on graphite and aromatic molecules. There was also inserted a symposium of eight papers, "From Benzene to Graphite", in which trends in aromatic properties could be surveyed in their broader aspects.

Some twenty-four papers dealt with various aspects of the important subject of 'graphitization', by which is meant the transformation of amorphous carbon or of carbon compounds into structures becoming progressively closer to ideal crystal graphite. Graphitization in some ways resembles other forms of bond rearrangement in polymer formation. However, elimination of foreign atoms is frequently a prerequisite and such atoms can 'block' graphitization in certain cases. New investigations based on some of the more familiar methods of studying the process of 'coking' have now been diversified by detailed measurements of carbon formation during the progressive charring of specific organic molecules, such as dextrose or sucrose, and following the electron spin resonance and infra-red absorption (Brown and Turkevich, 5; Singer, Spry and Smith, 6)*. An interesting chemical variant of partly graphitized carbon, stemming from hexamine and containing considerable proportions of nitrogen, was described by Riley (Barniecki and Riley, 34). Suggestive applications of some of these more novel techniques to coals were described by a number of authors.

About twenty papers presented detailed experimental or theoretical studies of the physical properties of carbon. Mathematical computations of energy-levels in idealized graphite and smaller macromolecules (Corbato, 21; McClure, 22; Haering and Wallace, 23; Pullman, 28; Mateon, 29) show very considerable refinements compared with the earliest work in this field. Discussions of the mechanical properties of carbons at high temperatures (72, 73) and of the energy exchange between graphite surfaces and gas molecules (18) are of obvious technical as well as academic interest. Electron microscope and electron diffraction studies on artificial graphites (Tsuzuki, 13) show dislocations the comparatively large dimensions of which do not appear to be fully explained. Some theoretical aspects of 'aromatic hole defects' and 'claw defects' in graphite were also discussed (Ubbelohde, 31) in relation to known experimental behaviour. Experimental studies of magnetic properties of partly ordered carbons (Pacault, 32; Adamson and Blayden, 8) have now been carried to a very considerable degree of precision.

There were only nine papers dealing more or less specifically with the chemical reactivity of carbons; this part of the programme could undoubtedly have been extended considerably, though it would have drawn somewhat different participants to the Conference. Interesting chemical techniques of testing for the presence of surface groups by methylation, amide formation, chlorination, and the formation of other surface 'derivatives' were discussed (Boehm, Hoffmann and Clauss, 53; Garten and Weiss, 59). Some striking examples were shown of highly localized promotion of the oxidation of graphite by surface catalysts such as iron, gold or silver (Hennig, 56).

Papers on graphite oxide (Clauss, 37), on 'red carbon' (Schmidt, Boehm and Hoffmann, 46), on the synthesis of diamond by members of the General Electric Co. (Tracy Hall, 35) and on graphite whiskers (Meyer, 14) gave tantalizing glimpses, but only glimpses, of new possibilities in the chemistry of carbon. On the other hand, five papers presented on the crystal compounds of graphite emphasize the growing interest in this field. A whole range of inter-related new compounds has been prepared by Crofts (36), who discussed some of the conditions for their formation. Various properties of graphite/bromine were described by a number of authors, and the salt-like model of potassium/graphite was also discussed (Ubbelohde, 38).

Finally, experimental studies on large aromatic molecules such as violanthrene or anthanthrene may be mentioned. Akamatu and Inokuchi (30) described the semi-conductor properties of a substantial group of molecules of this type, which have interesting analogies with graphite. Semi-conductor properties were likewise reported for semi-quinone types of complexes (Eley and Inokuchi, 2). The photo-conduction in single crystals of naphthalene, anthracene, tetracene, phenanthrene, 1-2-benzanthracene, 1,2,5,6-dibenzanthracene, diphenyl, terphenyl, pyrene and chrysene (Lyons, 1) adds weight to the slightly alarming conclusion that the modern physicist who hopes to deal successfully with the problems of carbon cannot afford to ignore quite recondite aromatic organic chemistry.

RECENT DEVELOPMENTS IN CLOUD PHYSICS

THE summer meeting of the Royal Meteorological Society, held in Glasgow during July 3–5, began with a lively and well-attended discussion on cloud physics. The meeting, which was held in the Department of Natural Philosophy, University of Glasgow, with Prof. P. I. Dee in the chair, was delighted to welcome Prof. C. T. R. Wilson, now in his eighty-ninth year.

Dr. B. J. Mason (Imperial College of Science and Technology, London) began by describing the results of some recent experiments, carried out in collaboration with J. Hallett, E. J. Langham and J. Maybank, on the supercooling and nucleation of water and on the growth of ice crystals from the vapour. Observations on the freezing of large numbers of droplets of distilled water, ranging from 10μ to 1 cm. in diameter and suspended at the interface of two immiscible liquids in order to avoid the nucleating effects of solid surfaces, had established proportionality between the logarithm of the droplet volume and its freezing temperature for a constant rate of cooling. Such a relationship appeared to characterize the heterogeneous nucleation of water droplets containing small foreign nuclei, and is probably associated with the fact that the ice-nucleating ability of atmospheric aerosols increases logarithmically with decreasing temperature. Dr. Mason went on to describe very recent experiments which had been successful in purifying water to such an extent that droplets could be regularly supercooled to temperatures ranging from −41° C. for 1-μ droplets to −33° C. for drops 1 mm. in diameter, at which freezing occurred spontaneously without the aid of foreign nuclei. The empirical relationship between droplet volume and nucleation temperature, which differed from that representing heterogeneous nucleation, showed good agreement with theory.

Photographs taken of freezing droplets revealed that, in some cases, solidification was accompanied by rupture of the ice surface and the liberation of a number of small ice splinters. This suggests a mechanism by which the numbers of ice crystals in clouds may be rapidly increased.

In an attempt to discover the nature and origin of atmospheric ice nuclei, tests had been made of the nucleating ability of various types of soil particles and mineral dusts, and had revealed that a number of silicate minerals such as kaolinite, microcline and some of the micas were effective at temperatures greater than −15° C. but that the more common silicates were relatively inactive. However, several types of nucleus became more effective once they had been involved in ice-crystal formation. Thus when ice crystals, formed on various silicate particles initially active only below about −20° C., were allowed to evaporate by warming them to very near 0° C. in a dry atmosphere, they left behind nuclei which were thereafter effective at temperatures as high as −5° C. Dr. Mason suggested that although most of the particles carried up from the ground can initially form ice crystals only at the low temperatures associated with the high cirrus clouds, when the crystals evaporate they may leave behind pre-activated nuclei, which may later seed lower clouds at temperatures only a few degrees below zero. This may explain why the tops of shower clouds sometimes show signs of glaciation at temperatures as high as −6° C., although nuclei active at these temperatures are rarely detected in surface air.

Finally, Dr. Mason used a series of photographs to illustrate the growth of ice crystals on a fine fibre running vertically through the centre of a water-vapour diffusion chamber. Clear-cut changes of crystal habit—from hexagonal plates → needles → hollow prisms → plates → stellar dendrites → plates → prisms—took place along the length of the fibre, over which the temperature varied from 0° C. to −40° C. These closely imitated the changes occurring in natural snow crystals. That the relative growth-rates of the basal and prism faces of ice crystals should change so abruptly and so often is very puzzling, but these experiments had clearly shown that the temperature and not the supersaturation of the environment is primarily responsible. The supersaturation is, however, important in determining the growth-rates of the crystals and the development of dendritic forms.

Recent measurements of condensation nuclei, cloud particles and rain, made from aircraft of the Meteorological Research Flight, Farnborough, were described by Mr. R. J. Murgatroyd (Meteorological Office). Raindrops measured at the surface commonly have diameters of 0·5–5 mm., and occur in concentrations of 0·1–1·0 per litre, whereas condensation nuclei have diameters of 0·01μ or more and concentrations of 10^6–10^7 per litre near cloud base. One of the main problems in cloud physics is to trace how raindrops develop after condensation on these nuclei.

Measurement of the total numbers of condensation nuclei from an aircraft by means of a Nolan–Pollak photo-electric counter indicated that concentrations over the land, particularly near industrial areas, are considerably greater than over the sea. Numbers decrease rapidly with height, the profile of concentration in the vertical being mainly determined by atmospheric stability. Cloud droplets, which were measured by impaction on magnesium oxide or oil-coated slides, are usually 10–30μ in diameter with concentrations of 10^4–10^6 per litre, so that only a fraction of the available condensation nuclei are apparently involved in the production of cloud. The most active will be the larger hygroscopic nuclei, probably of sodium chloride, and Mr. Murgatroyd described how the concentrations and sizes of salt nuclei are determined by collecting them on slides coated with a gelatine impregnated with silver nitrate. These particles are mainly in the range 0·5–10μ in diameter with concentrations of 10^2–10^3 per litre, and their vertical distribution is again controlled by atmospheric stability and the nature of their source. In these concentrations they are likely to be associated with only the largest cloud droplets, and it is these which will probably grow to raindrop size by coalescence.

Precipitation elements (greater than 100μ in diameter) were sampled by exposing a thin aluminium foil from the aircraft, and measuring the indentations produced by the particles on impact, a technique developed by the Mechanical Engineering Department of the Royal Aircraft Establishment, Farnborough. It has been found that small cumulus clouds, a few thousand feet thick, contain droplets about 100μ in diameter in concentrations of 0·1–1·0 per litre, which is of the same order as the concentration of raindrops at the surface. Examples were also given of the way raindrop sizes vary with height in layer clouds at temperatures above freezing, particles growing to raindrop size by overtaking and amalgamating with smaller droplets falling at slower speeds. The same technique is also being used to examine the development of rainfall by the Bergeron mechanism, which involves the ice-phase. Crystals in cirro stratus cloud rarely exceed 250μ in diameter, but in alto stratus and nimbo stratus snow flakes of 1–2 mm. diameter, increasing in size as they fall, are found. There is some size decrease as they melt at the freezing-level and then further increase during the rain stage below. Conditions in cumulo nimbus clouds are much more complex, liquid water drops often being found at temperatures of −10° C. to −30° C. The particles are larger and greater in number than in frontal clouds. In each case a size spectrum of precipitation elements can now be measured at all levels, and it seems likely that it will soon be possible to obtain reasonably complete cross-sections of particle distributions in frontal systems, and study the way they are developing to produce the rainfall observed at the surface.

The discussion took a new and interesting turn when Dr. T. W. Wormell (Cavendish Laboratory, Cambridge) described the results of recent work on electrification processes associated with precipitation near the ground.

The introduction of conducting particles, cloud particles or precipitation elements, disturbs the normal ionic equilibrium in the atmosphere and the particles may acquire considerable charges. The importance of such processes has been emphasized of late by Ross Gunn. In the presence of an electric field, and of droplets with appreciable fall-velocities, other effects of selective capture are likely to be of greater importance.

Once precipitation has started, the effects of splashing may seriously affect electrical observations at the ground and, indeed, cause difficulties in any type of observations. Recent work by Adkins at Cambridge has emphasized the importance of such effects; there may be copious production of ions at the ground and a rapid vertical variation of field in the lowest layers of the atmosphere. Further, laboratory work by Hon, also at Cambridge, showed that the continuous splashing of distilled water on many types of target builds up a space-charge of negative large ions which, if not removed, completely alters the effect attending subsequent individual splashing processes.

During quasi-steady rain the electrical effects are often feeble, being comparable in intensity with those of fine weather. According to a recent systematic study by Chalmers, the typical effect in such conditions is a negative potential gradient near the ground accompanied by a downward total current (convection current on rain plus ionization current). In other words, the total current into the ground is in the reverse direction to the ionization current. Chalmers suggests that there is in the upper part of a nimbo stratus cloud some electrification process which gives the top of the cloud a positive charge, with a negatively charged region beneath; and a second process lower down, beneath the freezing-level. Dr. Wormell suggested that this second process might be due to splashing at the ground and turbulent diffusion upwards of a negative space charge on slow moving ions. The electrification in the upper part of a nimbo stratus cloud is of the same sign as the main electrification of a cumulo nimbus, and it is conceivable that the mechanism is the same. It has been common of recent years to assume that this process involves ice. Processes which have been discussed include riming, glaze ice formation and the friction or violent collision of ice particles with different electrical properties. On the other hand, the writings of C. T. R. Wilson and Vonnegut demand a reconsideration of the possibility of influence mechanisms, and the common assumption that a thunderstorm necessarily contains ice in its upper portion has been challenged.

Dr. Wormell felt that the nature of the predominant charging mechanism in thunder clouds is still far from settled, that we still lack the information necessary to make a reliable quantitative assessment of the ice processes, particularly in the presence of an electric field, and that influence mechanisms cannot yet be finally dismissed.

The meeting owed much to excellent arrangements made by the staff of the Department of Natural Philosophy, who were very generous hosts.

B. J. MASON

HILL CLIMATE

ON the second morning of its summer meeting held on July 4 and 5 in the Department of Natural Philosophy, University of Glasgow, the Royal Meteorological Society directed its attention to problems of hill weather. The topics discussed were not peculiar to this branch of meteorology, as they included such general considerations as the information we have and how it can be used; the information we need and how it can be obtained; and the correlation of non-meteorological field data with weather or climatic factors.

As the main sink for observations, and the chief source of information, the Meteorological Office is the recipient of most technical and academic requests for help and advice, so it was appropriate that Mr. R. Cranna, of the Edinburgh Office, should provide the introductory paper on "Problems of Hill Climate". He quoted a number of examples to show that, apart from water balance and land utilization studies, many specific inquiries were being received which could not be adequately answered. Looking further ahead, water supply seemed to be emerging as a limiting factor in industrial development, and he foresaw that light industry might have to move to where water is available, in which event the Meteorological Office would find itself with a much bigger demand for information about hill climate. These inquiries would be for detailed wind and temperature data for building design; wet-bulb data for cooling towers; humidity data for air conditioning; and rainfall data for sewer and drain design. Reviewing the sources of data, Mr. Cranna showed that the Scottish network of climatological stations is very open, and until fairly recently was concentrated on or near the coast. New stations set up or contemplated have improved the inland network, but vertical distribution is poor. Although one-fifth of Scotland is above 1,250 ft., there is only one station at about that height, and none higher; and since Ben Nevis Observatory was closed fifty years ago there has been no place in Scotland at which variations of weather with altitude can be studied without complicating factors. Most of the stations are set in the bottoms of glens in an effort to attain the standard ideal site—a bowling green on an infinite plain—and there is a real need for more observations on slopes. Too much of existing information is about valley climates in hill country. The observations themselves might be modified, particularly as many stations report only once daily at 0900 G.M.T., and as an example of possible improvement it was suggested that maximum and minimum wet-bulb thermometers should be part of the standard equipment.

Mr. R. W. Gloyne, also from the Meteorological Office, Edinburgh, spoke first of the classification of dissected country. There already exist concepts of ground configuration which attempt to express departures from the infinite plain, and in a brief review of some of these concepts Mr. Gloyne summarized the meteorologists' experience as indicating that, very roughly, a vertical irregularity affects local weather over a distance of about one hundred times the height. Some measure of 'ruggedness' could be useful in interpreting local climatic differences. He then gave a sketch of a possible mathematical description of a land cross-section that incorporates estimates of mean slope, ruggedness, and the extent of contact between the ground surface and the atmosphere above it.

Next he turned to climate and plant growth, and as a basis for his argument accepted the conventional definition of the growing season as the "period of the year when mean air temperature remains above 42° F.". From records in the same broad region, but at different altitudes, it was shown that the effect of increased altitude is to decrease the mean annual air temperature without any marked effect on the amplitude of the approximate sine wave, that is, the two curves are nearly parallel. The part of the curve lying above the intercepts of $T=42$ will always be shorter for the higher altitude station, but simple geometry shows that the reduction is relatively less when the amplitudes are great, that is, the change in length of growing season with altitude will be more marked in an oceanic climate than in a continental climate. Some regional regressions demonstrated the point clearly. For height H (unit, 100 ft.) and growing season L (days) the relation for southern Scotland is $L=242-4\cdot4\ H$; for south Devonshire it is $L=365-9\cdot0\ H$; that is, the shorter Scottish season is only half as sensitive to change in altitude as that of Devon. Comparisons with other parts of the world included Conrad's formula for Switzerland ($L=268-2\cdot1\ H$; reference level $T=43°$ F.), giving at the height of Ben Nevis a growing season of about 150 days. From the old temperature records, $L=0$ on top of Ben Nevis, and from Gloyne's equation $L=50$, but this involves a long extrapolation. The variation of growing season with altitude is obviously a very sensitive climatic discriminant.

The remaining papers came from outside the ranks of meteorology, two of them from the University of Glasgow being accounts of field-work in which attempts were made to interpret findings in terms of weather. Dr. D. H. N. Spence (Botany Department) outlined some of his ecological work on plant communities in Shetland, Rhum, the central Highlands, the Faroes and Iceland. Where there is a combination of stable soil and protection from wind (as, for example, close to a stone wall in otherwise exposed areas) a relatively close-growing community of mixed grass and heath is found, but away from such shelter it is possible to find a small number of arctic-alpine species of plants growing in the open among rock debris that consists of small stones over finer material. These sites, occurring at different altitudes in the different regions, are characterized by frost-heaving and slipping of the soil so that they occur within what is broadly the same environment everywhere. Specification of this environment is far from complete, but first attempts at correlation suggest that the mean air temperature of the warmest month is an important climatic element in it.

Soil slip was the main factor in the survey from Mr. C. A. Halstead (Geography Department) of some of the surface features of hills in southern Scotland. Between 2,200 and 2,700 ft. there is evidence of an instability in the cover of soil and mountain-top debris, the downhill movement producing terraces having a tread of the order of ten feet wide, a riser of the order of a foot, and a length of about forty feet. The treads have grassy vegetation with peat; the risers have blocky faces with bilberry. Isolated blocks of rock below such terraces appear to be sliding down-hill, producing bow-waves of turf, and grooved tracks of disturbed vegetation behind. He suggested that these features are related to a zone of maximum frequency of alternating frost and thaw. To test this speculation he has devised a simple instrument to measure the frequency with which soil temperature passes through freezing point, and is hopeful that it will help in future studies of moving soils and sliding boulders.

The remaining paper gave added point to Mr. Cranna's regret about lack of Scottish stations above 1,250 ft. Lieut.-Col. P. D. Baird (Geography Department, University of Aberdeen) has been trying to use a local site for his ice and snow studies, and to this end has himself maintained weather observations at 4,120 ft. on Ben Macdhui since February 1956. Here, just below the summit, is a near-permanent snow patch and on this, in spite of damage and difficulties produced by high winds and icing, he has been able to obtain records of temperature, humidity and wind speed throughout the period. During May–October 1956, the record was complete, and a comparison with Braemar records for the same period, and then with the long-term averages for Braemar, led him to an estimate of the probable annual cycle of mean monthly air temperatures on the mountain. On this basis, the mean annual temperature is just below freezing point. Photographs were used to show the contraction of the snow patch during the summer, the drift of 30-ft. depth just surviving in 1956, but not in 1955, and—confidently—it cannot survive in 1957. Time was too short for more than a very brief discussion of the ablation process, but it seemed clear to Col. Baird that air conduction and convection play an overwhelming part in it, that is, the dominant factors are aerodynamic rather than radiative.

The arduous mountain ascents, often in bad weather, need have been made much less frequently if there had been an automatic weather station available, but there has been no British development of such an aid to climatology. Much more to be regretted is the complete absence of any manned mountain weather station. Other less wealthy countries regard these as essential, and Col. Baird's final plea was for the establishment of at least one in the British Isles.

The brisk discussion brought out useful criticisms, comments and questions from physicist, climatologist, geographer, and ecologist, and it was exhaustion of available time that forced its closure by the chairman.

H. L. PENMAN

ENDOCRINOLOGICAL PROBLEMS IN AGRICULTURE

By DR. I. W. ROWLANDS

Agricultural Research Council Institute of Animal Physiology, Babraham, Cambridge

THE rapid growth of the science of endocrinology beginning about thirty years ago arose from the discovery that the pituitary gland regulates body growth and the functional activity of the gonads and other endocrine organs. The past three decades have witnessed the separation and purification of growth hormone (somatotrophin), thyrotrophin, gonadotrophin (follicle-stimulating hormone and luteinizing hormone), adrenocorticotrophin and prolactin (or luteotrophin) from the pituitary gland and the chemical characterization of steroid hormones, oestradiol, progesterone and testosterone from the gonads, together with many of their metabolites from urine. A variety of substances having hormone-like actions (for example, diethylstilboestrol) have been synthesized, and in more recent years, a wide range of pure hormones have been isolated from that endocrinological enigma, the adrenal cortex. Armed with these new products, physiologists and biologists have attempted meanwhile to appropriate to each its precise biological function and to determine its role in the complex hormonal mechanisms which exist in the animal body. One important result of the extensive studies made in laboratory animals is the absence of any great measure of uniformity in the response of different species to the same hormonal stimulus. Our understanding of the role of hormones in the endocrine mechanisms of the large domestic species cannot, therefore, be obtained by inference; every species requires separate and individual investigation.

The Agricultural Research Council, in October 1952, assembled a committee known as the Technical Committee on Endocrinology consisting of eight specialists in various branches of the subject, with Dr. S. J. Folley as its chairman, to keep under review all endocrine problems in farm animals, and to recommend to the Council research projects within this field which it considered to be of value to the farming community and also those which would advance basic knowledge. After between three and four years work, during which a total of twenty-three scientific memoranda on a wide variety of subjects were prepared and discussed by its members and co-opted specialists, the Committee has submitted a report to the Council. Some of the earlier reviews have become out-dated by the rapid march of events in this science, so that publication of all the papers as a book is being withheld; but in view of the breadth of their scientific interest a list of titles and dates of preparation of memoranda is being prepared by the Council* which will be made available on request to interested research workers. Memoranda selected from this list will be sent on application.

The earlier memoranda concern the regulation of the reproductive processes. They include the role of external stimuli, for example, daylight and day-length, on hormone secretion and the various neuro-hormonal mechanisms which more recent work has exposed. In regard to the former, attention was directed to the need for further fundamental studies on the mode of transmission of the light stimulus to the pituitary gland which is necessary for the evocation of reproductive activity in animals breeding seasonally. Its elucidation would supply a background of information which would be useful to workers interested in the hormonal induction of oestrus and fertility in anoestrous sheep, on the lactational performance in cows and in egg-production in hens. Two of the memoranda on neuro-hormonal mechanisms favour the extension of research into the mode of release of hormones, especially those from the pituitary gland. Much of this work is of considerable academic interest to the neuro-endocrinologist and has also an important bearing on animal husbandry. The vigorous prosecution of research is recommended into (*a*) milk ejection in cows, (*b*) sperm transport in the female reproductive tract, (*c*) the temporal relation between mating and ovulation, (*d*) parturition and (*e*) suckling. The elucidation of the mechanism integrating the continuous release of the anterior lobe hormone (prolactin) and the intermittent, reflex stimulation of secretion (oxytocin) from the neurohypophysis is of special interest.

Further advances in many branches of endocrinology are seriously impeded by the lack of assay methods of sufficient precision and sensitivity of identify and measure the very small amounts to various steroids circulating in the blood and tissues of normal animals. Special mention is made of the bio-assay of progesterone as being the key to the problem of evaluating the relative activities of the corpus luteum and the placenta in the maintenance of foetal life. Of no less urgency is the need to discover sensitive methods for the bio-assay of adrenal hormones, in order to elucidate the metabolism of corticosteroids in ruminants as a preliminary to further research into physiological abnormalities such as parturient paresis and ketosis in farm animals.

---

* Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1.

The problem of increasing the reproductive capacity or prolificacy of farm animals continues to attract a large amount of attention. In sheep the object has been the increase in the number of twin lambs by hormonal (gonadotrophic) stimulation of the ovaries during the normal breeding season or during ancestrus. Very promising results have been reported on the use of a single injection of serum gonadotrophin preceded by a short course of injections of progesterone as a method for the induction of ovulation and œstrus in the ewe during ancœstrus; but the method will remain impracticable for large-scale use until it can be simplified. Even then, the usefulness of the procedure might well be restricted by agricultural considerations, such as shortage of good grazing.

In polytocous species, prolificacy would be increased if a larger number of the eggs which leave the ovaries became fertilized and developed normally to term. Pre-natal mortality at various stages of the reproductive process in the pig is known to reduce, to an important extent, the number of young that are born. The causes of embryonic mortality in this and other species are largely unknown but would seem to be varied in character. Thus, preliminary work has indicated the existence of strains exhibiting high and low levels of fœtal loss, and of a genetic factor carried by the boar which facilitates implantation of the developing egg and the maintenance of gestation in his daughters. This and other factors concerned in fertilization, implantation and the maintenance of gestation are being investigated in a programme of research into the physiology of reproduction in the pig.

Breeding experiments to improve the genetic constitution of farm animals take many years to complete, because of the long interval between succeeding generations. Experiments on the transfer of fertilized eggs are being performed, however, to reduce the generation-interval in cows. These make use of the fact that the ovaries of the new-born calf are very sensitive to stimulation by gonadotrophins and that ovulation can be induced in very early life. The aim is to transfer eggs after fertilization from the uterus of the calf to that of a mature cow, so that the interval between generations can be shortened by a period equivalent in length to that taken by the newly-born calf to reach full sexual maturity. This technique, when perfected, will have various applications in the breeding of high-quality beef and dairy cattle.

Research into the endocrinology and physiology of lactation is fully justified by the nutritional importance of milk as an agricultural product. The dependence of lactation, no less than that of mammary growth itself, on hormonal action is commonplace. An immense amount of work has been done already, but the complete story is not yet unfolded. A memorandum provides many suggestions for future studies to unravel the action of anterior pituitary hormones on milk-secretion. It urges the use of hypophysectomized goats as a substitute for the cow for the study of the influence of these hormones in the maintenance of lactation.

A further indication of the complex nature of the hormonal control of lactation is given by the fact that milk-secretion in goats, which ceases abruptly after bilateral adrenalectomy, could only be maintained after this operation by the synergistic action of a mineralocorticoid (deoxycorticosterone) and a glucocorticoid (cortisone). For future work, it has been suggested that the composition of the milk secreted in response to injected corticosteroids should be carefully analysed to give a possible lead to the precise role of these hormones in lactation.

Extensive trials were given during the Second World War to the use of synthetic œstrogens, thyroxine and iodinated proteins for the induction of lactation in virgin heifers and barren cows as a practical method of augmenting the national milk-supply. No entirely satisfactory method was discovered of counteracting the great variability in the response of different animals to treatment with œstrogens, and the production of deleterious side-effects by these substances led to the abandonment of the project. Recent investigations have shown that a greater measure of control of mammary response to œstrogen is possible if progesterone is used simultaneously. This introduces new hope; but the problem of dissociating the untoward actions of œstrogen from its mammogenic and lactogenic properties awaits solution. Studies should be made of the factors governing maximum udder growth during pregnancy and for this research work it was recommended that poor-quality cows in late pregnancy might be used.

The evidence presented on the usefulness of hormones as agents to secure rapid growth and fattening of young animals is equivocal. Experiments on small animals have shown that hypophysial growth hormone increases appetite and the deposition of protein, but that unrestricted feeding, which may render any project uneconomic, is required to overcome the effect of the hormone on the depletion of fat. There is, however, an indication that the deposition of protein depends on the availability of insulin. The results obtained on the fattening of pigs using stilbœstrol, androgens and anti-thyroid drugs (thiouracil), too, have not been an unqualified success, although results offering more promise have been obtained from the combined feeding of stilbœstrol and thyroxine to castrated male pigs. The widespread interest in the United States concerning the use of stilbœstrol as a fattening agent for sheep and cattle called for the initiation of similar work in Britain. At the same time, concern was felt about the coincidental production of untoward side effects (for example, hyperostosis) by the œstrogen, but ways were suggested by which these may be counteracted. Furthermore, the possible contamination of the carcass, especially the fat, with œstrogen should not be overlooked.

Two other memoranda deal with certain aspects of the relation of hormones and nutrition in animals, and many recommendations have been made for further research in which chemical methods for the determination of seminal constituents could be employed to evaluate the effect of hormone administration in animals under various conditions of nutrition. Moreover, the effects of specific food components, for example, vitamins, trace elements, amino-acids and fatty acids, on testicular activity could be assessed by this method. The need for co-incidental studies on the spermatogenic function of the testis and the fertilizing capacity of sperm and the advantages to be gained from the use of monozygotic twins are apparent.

The outstanding problems concerning the role of hormones in the control of reproduction in birds are mentioned in a memorandum which also expresses concern over the lack of endocrinologists in Britain who are interested in the fowl as a laboratory animal.

This animal deserves a far greater measure of scientific investigation than it now receives, especially in view of the already great, and still growing, value of the poultry industry. The memorandum recommends that efforts be made to attract young workers into this field of research to investigate such problems as the endocrine control of the secretory activity of the oviduct, the role of hormones in the moult and broodiness in hens and the action of hormones on the differentiation of sex and on gonadal development. The Poultry Research Centre has facilities for intensifying its research programme along these lines if the scientists become available to conduct the work.

There would appear to be a close connexion between endocrinology and genetics; but there are, in fact, only a few examples in support of this contention. The relation between these two subjects was discussed at a meeting to which eminent geneticists were invited. Much closer co-operation than had previously existed between workers in these two sciences was thought desirable for their mutual benefit in the resolution of many complex problems.

No direct approach has been made to the problem of infertility due to physiological causes in farm animals, except in so far as it may arise from the ingestion of œstrogenic substances in pasture plants. Such a substance has been isolated from red clover and some British grasses in concentrations equivalent to 2–6 μgm. of the naturally occurring œstrogen per gram of the dried plant. It would not seem to be directly responsible for the rise in percentage of non-fatty solids of the milk of cows put out to graze after prolonged periods of stall feeding; but it is considered feasible that the intermittent occurrence of short periods of herd-infertility which has been reported in cattle might be attributed to sudden changes in the amounts of œstrogen ingested. If this be the case, failure to reproduce would most likely result from the inability of the blastocyst to become implanted because of the disturbance to the œstrogen–progesterone equilibrium.

The reviews which have been discussed by the Committee by no means exhaust the topics that could be presented on endocrinological problems in agriculture. Nevertheless, they give a broad glimpse of the many pathways along which future research could benefit the farming industry. Already, the first steps have been taken along several of these paths.

A CODE FOR PROTECTION AGAINST RADIATION

FOR the first time a comprehensive manual on the protection of radiological workers has been issued by the Office of the Prime Minister and First Lord of the Treasury (Atomic Energy), Ministry of Health, Department of Health for Scotland and Ministry of Health and Local Government for Northern Ireland[*]. This does not imply, however, that radiation protection has hitherto been neglected, either in hospitals or by other responsible authorities in Britain. So long ago as 1921 the British X-ray and Radium Protection Committee was formed, largely as a result of the pioneering work of Prof. Sydney Russ, "with the object of arresting the sequence of casualties to X-ray and radium workers". Many of the recommendations of the British Committee were adopted by the International Commission on Radiological Protection in 1928, and the Committee continued in being until 1948, when it published the seventh and last revision of its report. For more than a quarter of a century the recommendations of the British Committee formed the basis of radiological protection in Britain. These recommendations have been supplemented over the past ten years by an "Introductory Manual on the Control of Health Hazards from Radioactive Materials", prepared for the Medical Research Council by the Ministry of Supply, Atomic Energy Research Establishment.

The new "Code of Practice for the Protection of Persons exposed to Ionizing Radiations" is designed to meet the needs of an age in which the production, variety and uses of radioactive materials have enormously increased. This informative and extremely useful manual has been prepared by a distinguished committee, with Sir Charles Darwin as chairman, which was set up under the Radioactive Substances Act to advise Ministers on questions of radiation protection. The Code is based on the scientific findings of other bodies, notably on the recommendations of the International Commission on Radiological Protection (1955) and on the Medical Research Council's report on "The Hazards to Man of Nuclear and Allied Radiations" (1956).

The general rules of the Code make it clear that the officer in charge of a department in which ionizing radiations are used is responsible for the radiological safety of the staff. It is advised further that one member of such a department should be designated as safety officer, to be responsible for the necessary protection measures. The word 'must' is used to indicate essential requirements and the word 'should' reserved for desirable but presumably not always necessary or practicable requirements. Every employee must, in future, sign a statement that he has read and understood those sections of the Code applying to the circumstances of his work.

The Code of Practice is presented in two parts: Part *A* deals with the use of X-rays for diagnostic purposes and the use of X-rays and γ-ray beam units for therapeutic purposes; Part *B* concerns the medical uses of radioactive isotopes, sealed or unsealed. In both parts rules of protection are laid down without detailed specifications about installations or techniques, but no important points are overlooked. Part *A*, for example, contains all the minimal requirements for X-ray tube housings, diaphragms, fluorescent screens, observation windows, protective clothing, etc., and Part *B* gives most valuable information on the types of laboratory required for different levels of activity of radioisotopes of various defined grades of toxicity. Practical details are also given relating instrument response to levels of contamination and describing sensible procedures to be followed if radioactive materials are spilt. No rules are yet given on the disposal of radioactive waste; this problem, which impinges on some of the responsibilities of local authorities, is still under consideration.

---

[*] Code of Practice for the Protection of Persons exposed to Ionizing Radiations. Pp. iv+83. (London: H.M. Stationery Office, 1957.) 8s. net.

One half of the eighty-odd pages of the manual is given to a well-planned supplement which admirably summarizes the essential findings of the International Commission on Radiological Protection (1955) and gives the technical information necessary for implementation of the rules of Parts *A* and *B*. This section also includes a glossary defining all the technical terms appearing in the manual.

Comparison of the new Code with the older recommendations illustrates the increasingly cautious attitude now taken towards any irradiation of human beings additional to that received from natural sources. The earliest recommendation of a 'tolerance dose' of 1 r. per week has been gradually abandoned in favour of a 'maximum permissible dose' of 0·3 r. per week, now accompanied by still stricter provisions in terms of maximum cumulative doses for whole-body exposure. The limits applicable for exposure up to thirty years of age and per decade thereafter are equivalent to an average weekly dose of 0·1 r. "This is one-third of the maximum permissible weekly dose. In the case of long-term exposure, the protection must be planned accordingly" (Code, p. 52).

On the other hand, less emphasis than formerly is placed upon the necessity for regular blood counts. Provided adequate radiation monitoring is carried out in all circumstances involving occupational exposure, routine blood counts are suggested only in the case of workers who receive average doses exceeding one-half the maximum permissible weekly level averaged over a period of three months, and in the event of a worker acquiring a significant amount of an isotope deposited internally. Presumably the Committee considered that doses of radiation insufficient to affect the blood count could be harmful and that a blood count therefore afforded insufficient security at the lower dose-levels. Even so, the blood count does offer a biological test which cannot be circumvented accidentally or intentionally by anyone, and which can give an indication of high doses which for a number of reasons could be missed by purely physical monitoring.

Hours of work receive no mention in the Code, although the British X-ray and Radium Protection Committee was forthright on this point, recommending a five-day week, "the off-days to be spent as much as possible out-of-doors and not less than four weeks holiday a year, preferably consecutively". No reason is given for this omission in the present Code. It is convenient administratively and it is probably correct to formulate regulations for radiation safety apart from rules about working hours but, in my opinion, it would be unwise to separate these considerations in the case of hospital radiological staff who, in their daily contact with the sick, are exposed to the risk of infection as well as to an agent noted for its toxicity to the blood-forming tissues.

A very great service, however, has been performed by Sir Charles Darwin and his colleagues in producing so useful and valuable a document, which has a field of application much wider than hospital radiological work. The manual must be in the hands of all those who use ionizing radiations in the National Health Service; it should—and almost certainly will—be beside all others who use ionizing radiations for any purpose whatever.

The Minister of Labour and National Service has recently issued a preliminary draft of a new Code of Regulations to safeguard workers employed in industry against the effect of ionising radiations (Factories (Ionizing Radiations) special Regulations: Preliminary Draft. Pp. 16. H.M. Stationery Office. 9*d*. net). The regulations deal with industrial X-rays and sealed radioactive sources. Draft regulations to deal with unsealed or open sources are in the course of preparation.

F. W. SPIERS

OBITUARIES

The Right Hon. Viscount Cherwell, P.C., C.H., F.R.S.

FREDERICK ALEXANDER LINDEMANN, Viscount Cherwell, was born in Baden-Baden on April 5, 1886, and died in Oxford on July 3, 1957. His father, a naturalized Briton who came from an Alsatian family of French loyalty, was a wealthy engineer; his mother was English. He shared with his father an interest in astronomy and in instrument-making; and physics and mathematics became his principal subjects when he studied at the University of Berlin under Rubens, Planck and Nernst.

His Ph.D. dissertation was completed in 1910; it was on the atomic heats of metals at low temperatures, and with Nernst he published some important papers on this subject. Altogether he produced nearly twenty papers before 1915; besides the atomic heat work they dealt with subjects as varied as a glass transparent to X-rays ('Lindemann glass'—published jointly with his physicist brother, now Brigadier C. L. Lindemann), astrophysics, and his well-known melting-point formula. The last, which was the subject of his first independent paper, was characteristic: his simple physical model of a crystal lattice melting when its atoms oscillate so violently as to hit their neighbours enabled him to relate, with a minimum of calculation, the melting-point of a material to its Einstein single frequency.

Lindemann's strong loyalty to Britain cut short all this work in 1914, for it took him to the Royal Aircraft Establishment at Farnborough, where he was one of several outstanding physicists who devoted themselves to the many problems arising in the new field of aeronautics. Most of his work was concerned with the instruments of flight; but he is best known for his diagnosis of the way to recover an aircraft from the hitherto fatal condition of spinning. He had learnt to fly, and he undertook the trials himself: their success matched his courage, and Lindemann's technique became a standard drill. It has been said that he was not a good pilot, but it should be remembered that there was no obligation whatever for him to fly, and furthermore that he had only one good eye. He doubted the advantages of binocular vision, and would point out that he "had not done too badly" at tennis without it. Indeed, he had won several championships in Germany and

Sweden before 1914, and competed honourably at Wimbledon after he had become Dr. Lee's professor of experimental philosophy at Oxford in 1919. In that year, incidentally, he published with F. W. Aston a paper on the possibility of separating isotopes which suggested many of the methods afterwards used.

Lindemann's appetite for action outside the purely academic plane may have been so whetted by his Farnborough experiences that he could not again settle into research with his pre-war vigour. In addition, the load of a chair and a department which had been almost moribund for many years may have limited his personal research. His papers appeared less regularly; the most outstanding were those with G. M. B. Dobson on meteors, with the important and correct conjecture that there was a warm layer in the Earth's outer atmosphere, and that with his father and T. C. Keeley on the instrument now known as the Lindemann electrometer. This originated in the need for a small, sensitive electrometer for use with the photoelectric cells of outstanding sensitivity that had been made under Lindemann's leadership in the Clarendon Laboratory. In the meantime, in one of the heroic ages of physics, the structure of quantum mechanics was being built, and Lindemann's contribution was a book—"The Physical Significance of the Quantum Theory", published in 1932—in which he developed with characteristic ingenuity and insight the applications of the principle of indeterminacy. The book was elegantly and concisely written, and still merits attention.

Lindemann's direction of the Clarendon Laboratory was for some time as diverse as the subjects of his papers; apart from photoelectricity there was no main line of steady research. This was rather hard on new research students, each of whom might have to enter a new field with a minimum of briefing. For the stronger men the system was good: their abilities had already been tested by the unusual and stimulating examinations which Lindemann had set, and their independence of thought and self-reliance were enhanced by their individual researches. If they succeeded, no professor could have been more generous than Lindemann in keeping his name out of their publications. But the result was a series of isolated researches in each of which much effort had to be expended in surmounting the difficulties of entering a new field, and the position of the Clarendon was still scarcely commensurate with its seniority among the world's laboratories. In 1933, however, Lindemann became one of the main sponsors of refuge for the Jewish scientists in Germany. He had been a constant visitor to the Continent since boyhood, and he appreciated very early the significance of the Nazi movement. Among those to whom he offered refuge was Prof. Franz (later Sir Francis) Simon, and under Simon's leadership the reputation of low-temperature physics at the Clarendon grew rapidly. At the same time, the survivors of the earlier 'sink or swim' phase were producing notable work.

It was not easy to convince Oxford of the needs of physics, or indeed of science in general. Even in 1939 there were only about six fellowships in physics in the whole University. Part of Lindemann's achievement is that he did ultimately succeed in awakening the University to the importance of the subject, with the result that the new Clarendon Laboratory was built and opened in 1939, and new fellowships were created. The new laboratory was the best of its kind in Britain, and fortunately the staff was kept substantially intact throughout the War to work on problems of microwave generation and isotope separation. This enabled the Clarendon to start research again, immediately after the War, with all the apparatus and techniques acquired in the meantime. Lindemann had come to the Clarendon when almost no research was being done; he left it, on voluntary retirement in 1956, a well-equipped laboratory with a great reputation. This end had constantly been before him and, while his way of attaining it had not been entirely the traditional one of personal example and leadership in research, the credit is his.

It is rare, but not unique, for a man of science to be closely associated with a statesman. J. H. Poynting wrote papers of the 'operational research' type at the request of his friend, Joseph Chamberlain. The latter's son, Austen, was among the friends of Lindemann, who had become well known in the 1920's to several senior members of the Conservative Party. His friendship with Sir Winston Churchill and their collaboration from 1932 onwards is part of our history. Their joint stand with Austen Chamberlain on the scientific possibilities of air defence in 1934 and 1935 was one of the factors which led to our being ready just in time for 1940. Here again, Lindemann's methods were not those usual to academic men. An individualist, he unsuccessfully stood for election to Parliament in 1937, while other physicists, with an equal sense of duty, had joined in a committee to help the Air Ministry directly. The happiest verdict on this, at times painful, difference may also be the true one: that the Air Ministry and the country benefited greatly from the committee's work, and from Lindemann's independent approach.

When the Second World War broke out, Mr. Churchill called Lindemann to the Admiralty as his scientific adviser, and when the former became Prime Minister in 1940, the latter moved to the Cabinet Offices; he was appointed a formal member of the Government as Paymaster-General in 1942. He remained in this post until 1945, when he returned to Oxford, and he became Paymaster-General again from 1951 until 1953 at Mr. Churchill's request. The flair for simple physical models that was evident in his scientific papers was invaluable in making clear to the Prime Minister in "lucid, homely terms" what the scientific issues were in any problem regarding new weapons. Lindemann's influence on the scientific policy decisions of the War, and from 1951 onwards, was great. He was always prepared to take an unpopular stand, as in 1940 when he refused to believe the accuracy of our bombing claims; his persistent scepticism revealed the facts, and resulted in a complete switch to radio navigational aids to bombing.

By no means all his advice would have been endorsed by other men of science. In particular, he could not resist the very quickness of his mind leading him to form a theory from a minimum of fact; and having once committed himself to the theory, he would be reluctant to accept any subsequent fact that disagreed with it. Moreover, behind a misleadingly aloof exterior he had great warmth of feeling, with strong likes and dislikes, so that his acceptance or contradiction of a particular point of view would sometimes much depend on how he felt towards the propounder. These factors—intense loyalty to his theories and his friends—detracted at times from the balance of his judgment; but when this has been admitted, there is much to be grateful for. His criticisms were courageous in expression and stimulating in effect. My own experience is coloured by the memory of his insisting on my being called to give my views on the reality of the *V2* rocket threat, to a War Cabinet meeting of 1943, despite the fact that he knew that I—much his junior and his pupil—was going to differ completely from his own conclusions; and although he was not right about the rocket, it was in part due to his prescience that we were not blind to the parallel threat of the flying bomb.

As a relaxation from the strain of Whitehall during the War, he pursued a long-standing interest in the theory of numbers. In 1933 he had published a very direct and elegant proof of the fundamental theorem of arithmetic, and he now followed this by a heuristic proof of formulæ for the frequency of occurrence of prime-pairs, prime-triplets and other combinations. Unknown to him, these formulæ, which he confirmed by counts, had been found by much more elaborate (and equally non-rigorous) methods by Hardy and Littlewood and by Staeckel, but Lindemann's methods were much simpler and more illuminating; no rigorous proof has yet been found.

In the field of nuclear energy, his advice must have been vital. For a long time it was doubtful whether he was convinced that a nuclear bomb was possible. The idea of such destructive power being available to human hands seemed to repel him so much that he could scarcely believe that the universe was constructed in this way; and it is perhaps against this background that some of the war-time decisions about nuclear energy should be construed.

After the War, he keenly supported the setting up of a separate Atomic Energy Authority, and he was a member of the Authority for the last three years of his life. He was also much concerned with general policy in science and technology, and he was intensely anxious to see both the cultural and material value of science more adequately appreciated in Britain and the status of men of science enhanced. He made speeches of impressive content on all these matters in the House of Lords. They sometimes resulted in controversy, but there will surely be universal agreement with this confession of faith which he made in a debate on university education on May 14, 1947:

"The function of a university teacher, as I see it, is to develop in young people the habits of exact and logical thought, to show them how and where the underlying facts can be ascertained on which conclusions are to be based, to indicate how the great minds of the past have tackled problems; to show what conclusions they have reached and how they have justified them, and, above all, perhaps most important of all, to arouse the students' curiosity and interest and stimulate them to the point of making the students desire to spend laborious days and nights in an effort to contribute themselves something towards the advance of knowledge."

Cherwell had an unusual range of honours. He was elected to the Royal Society in 1920, and he was awarded the Hughes Medal for 1956. He was created Baron Cherwell in 1941, a Privy Councillor in 1943, a Companion of Honour in 1953, and he was raised to a Viscounty in 1956. He received the Messel Medal of the Society of Chemical Industry, and the LL.D. degree of the University of Aberdeen.

He was not a professional physicist in the sense of having to make his living by physics, since he was wealthy enough by inheritance to have lived in comfort without working. His interest in physics was thus all the purer, and his independence the greater; at times he accepted no salary for his work for the Government. His will provides for substantial bequests to Christ Church and Wadham College, Oxford, and expresses the wish that these bequests be applied to the foundation of fellowships or studentships for teaching and research in the physical sciences, including astronomy.

Something of his personality will have been evident from this appreciation. His loyalties to Britain and to science transcended all his feelings and permeated the great width of his interests. His wit, his anecdotes, his arguments and his aloofness were the subjects of many 'high-table' stories. His aloofness, however, was easily penetrated by anyone in misfortune; he would go to much trouble to answer a request for help, or to provide help before it had been asked. He placed surpassing value on his friendship with Sir Winston Churchill and on the tenure of his chair; and he faithfully returned to Oxford in 1953 because, he said, the chair was the substance and politics the shadow. The very fact that at critical periods he was in the innermost circles of government and of international relations gave confidence to other men of science that their language and their thoughts would be understood in those circles; and as an ambassador of science when it was first entering directly into the destinies of nations, he commanded the respect and earned the affection of the statesmen with whom he so loyally worked.

R. V. JONES

Dr. Irving Langmuir, For.Mem.R.S.

IN an age of ever-increasing specialization, it is given to few to open up new vistas in many fields and to make notable advances in both academic and industrial worlds. Such a man was Irving Langmuir, whose recent death at the age of seventy-six has left such a gap in the select band of the élite of modern scientists.

Langmuir, who had been a teacher in the small academic Stevens Institute, Hoboken, New Jersey, was invited by Dr. Whitney, director of the Research Laboratory of the General Electric Co., Schenectady, to enter that Laboratory in the summer of 1909. Instead of being assigned some particular problem, Langmuir was given a free hand in following the various investigations current at that time. He was attracted to the problem of the cause of brittleness in drawn tungsten wire, which Coolidge had then recently developed, and suspected that gaseous impurities occluded in the wire might be the cause. Whitney suggested that he might examine this possibility in more detail, and thus started that series of monumental investigations on the interaction of gases with, and at, the surface of metals, with which the name of Langmuir will always be associated.

Apart from the implication of this work for the problem of heterogeneous catalysis, there emerged, in the form of as it were by-products of his work, fundamental inquiries such as the rigorous computation of the loss of heat from hot filaments, the mercury-jet vacuum pump, the nitrogen gas-filled incandescent electric lamp, the evaluation of the heat of dissociation of hydrogen and the use of atomic hydrogen in welding.

It is interesting to note that Langmuir extended his investigations on the processes of evaporation and condensation to the case of the alkali metals on tungsten, where evaporation of atoms, ions and electrons can be observed and the phenomenon of surface mobility most readily demonstrated. The recent developments in our theories of heterogeneous catalysis are beginning to emphasize the importance of these contributions carried out nearly thirty years ago.

Langmuir soon discovered that these reactions taking place with heated tungsten filaments and gases at low pressures involved but a single layer of atoms on the surface of the metal, which he likened to a checker-board of free valencies. Furthermore, from his studies on the reactions of carbon and its oxides at high temperatures, he concluded that the properties of adsorbed films should in general depend on the orientation of the molecules or radicals in the film with respect to the substrate, and that this hypothesis could be examined most conveniently at liquid surfaces. These inquiries resulted in the now famous series of papers published in 1916 and 1917, in which the concept of the orientated monolayer was developed and the evidence for molecular orientation at the surface of liquids tested by a series of ingenious and simple experiments.

It is of interest to note that this concept of molecular orientation at interfaces was being developed simultaneously but by very different paths by Prof. Devaux in Paris and Sir William Hardy in Cambridge. Such molecular orientation is due to the operation of short-range forces which vary in magnitude over different portions of the molecules concerned, and Langmuir extended this view of surface orientation to computation of the properties of binary liquid systems, making use of the hypothesis of independent surface action.

During the Second World War, Langmuir was engaged on the problem of screening by means of smoke and of the de-icing of aircraft. For a few years before his death, he, together with his colleague Dr. V. Schaefer, took up the problem in a new form, namely, the modification of clouds and the control of weather by the method of chemical seeding.

Those of us who have had the honour and the pleasure of long acquaintance with him and Mrs. Langmuir, and have seen both his experiments on the clean-up of nitrogen in the laboratory and his detection of black widow spiders with the aid of a flash lamp at Lake George, will always carry in their minds the memory of a man unspoilt by the many honours bestowed upon him, a man unrivalled in his power of observation and directness of thought, one who could impart his ideas to others with that simplicity which is the mark of the truly great and one whose friendship did not change with the years.

ERIC K. RIDEAL

NEWS and VIEWS

Union Astronomer at Johannesburg: Dr. W. H. van den Bos

DR. W. H. VAN DEN BOS, who retired at the end of 1956 from the post of Union Astronomer at Johannesburg, is one of a considerable number of astronomers who went abroad after studying astronomy under Prof. W. de Sitter at Leyden. He went to Johannesburg as Leyden observer in 1925, and shortly afterwards was taken on to the permanent staff as chief assistant. In 1941 he was promoted to the directorship of the Observatory. His chief interest has been in double stars, and it may fairly be claimed for him that he did for the southern hemisphere what Aitken had done for the northern—complete the survey of all stars down to a definite brightness and measure systematically at two or more epochs all the double stars he found. He has been recognized for many years as the leader in his chosen field, was president of the commission on double stars of the International Astronomical Union and kept up to date a compilation of all measures of southern double stars, now being incorporated with a similar compilation for northern stars. After his retirement he is spending a year in the United States measuring at the Lick, MacDonald and Yerkes Observatories the most important double stars, for which there are not adequate observers in the northern hemisphere. Astronomers look forward to the results of his new labours.

Dr. W. S. Finsen

DR. W. S. FINSEN, who has succeeded Dr. van den Bos, is an astronomer trained in South Africa, whose chief observing activities have also concerned double stars. He is, moreover, extremely interested in instrumental design and has himself constructed new delicate pieces of apparatus. He is best known for his stellar interferometer for measuring the closest and therefore the most important double stars. By the observation of the brightest stars, he has discovered new and very close doubles. He should prove a useful director of the Observatory in undertaking a new exact time service and in the construction and erection of a large reflector at a site away from Johannesburg at Hartbeespoort.

Regius Professorship of Physic in Cambridge: Prof. J. S. Mitchell, C.B.E., F.R.S.

PROF. J. S. MITCHELL, who has been appointed regius professor of physic in the University of Cambridge in succession to the late Sir Lionel Whitby, was born in 1909. He entered the Medical School of the University of Birmingham in 1926, and later won a scholarship to St. John's College, Cambridge; here he took a double first, including Part II physics. After completing his clinical training at Birmingham he qualified with the Cambridge M.B. in 1933 and became house physician to Prof. K. D. Wilkinson. A Beit Memorial Fellowship in the Colloid Science Laboratory at Cambridge under the supervision of Sir Eric Rideal was followed by a fellowship at St. John's in 1936, and he eventually became assistant in research in radiotherapy at Addenbrooke's Hospital, where he was closely associated with the late Prof. J. M. Ryle in the Department of Medicine.

During the War, after a period in the Emergency Medical Services, he was in charge of medical investigations in the National Research Council Laboratory at Montreal, until in 1946 he was elected professor of radiotherapeutics in the University of Cambridge. In his own department at Addenbrooke's he started regular joint clinics with physicians, surgeons and specialists in charge of special departments, and these have become an increasingly important factor in integration. His approach is always as a physician using radiation as a method of medical treatment. In research he has ranged widely, but of recent years his topics have included the design and conduct of clinical trials of new methods of treatment of cancer, the chemotherapy of cancer, the radiotherapy of malignant tumours with especial reference to the 30-million volt synchrotron and the clinical applications of radioactive isotopes. His considerable scientific attainments are matched by his kindness and concern for the well-being of his patients. He was made C.B.E. in 1951 and elected to the Royal Society in the following year. As regius professor of physic at Cambridge he is well equipped not only scientifically and clinically, but also by local knowledge of the organization of the University and of the region, to direct the development of the Cambridge Medical School.

Athanasius Kircher

THE magic lantern is said to have been invented by Athanasius Kircher, the date being given variously as 1646, 1664 or 1671. In the *Observer* exhibition held last summer in London he was featured, along with Lucretius, Ptolemy and Leonardo da Vinci, as "discovering a principle involved in Cinematography", and in a history of the silent film published last year in Germany—"Unsterblicher Film", by Heinrich Fraenkel—he is mentioned as having converted the camera obscura into a magic lantern. In his "History of Light", published in 1772, Joseph Priestley says with reference to Kircher, "we are perhaps, at this day, most obliged to him for his ingenious contrivance of the Magic Lantern . . . . Those who chuse to see Kircher's own drawing of this ingenious instrument will find some very fine ones in his *Ars Magna Lucis et Umbrae*". Whether or not Kircher did invent the magic lantern has been fully investigated by Dr. P. A. Houston (*Sci. Prog.*, 45, No. 179; July 1957); the investigations show that almost certainly Kircher did not invent the magic lantern and deserved the epithets given to him by a writer in the *Allgemeine Deutsche Biographie*. "I have gone into these works of Kircher in detail," he said, "because it was my purpose to show him as the charlatan he was. He had a many-sided education and great zeal, but only superficial knowledge, and no idea of method; he was a diligent worker, but he was neither reliable nor thorough. He was not the researcher for whom it is sufficient if the experts appreciate his work; what his nature required was the empty admiration of the so-called 'wider circles' and to retain this he stooped to falsification."

World Federation of Scientific Workers

THE fifth General Assembly of the World Federation of Scientific Workers was held in Helsinki during August 29–September 2. Fifty-three representatives from eighteen countries were present and the delegates included Academicians Chou Pei Yuan (China), A. I. Oparin (U.S.S.R.), I. Malek (Czechoslovakia) and Profs. J. D. Bernal and C. F. Powell (Great Britain). Apart from the discussion of internal affairs of the Federation, there were two symposia on "The Planning of Science" and "Scientific and Technological Training", respectively. The planning of scientific work has now become important in many countries with differing social and economic systems. This symposium provided a valuable opportunity for an exchange of ideas and information concerning the practical consequences of planning. The second symposium gave an opportunity for reviewing what had been achieved in this field in a number of countries. Many of the problems of curricula and organization are common to all countries and evidently arise from the rapidity with which science has developed in recent times. The sandwich courses which are being developed in Great Britain are an innovation as yet little known abroad. The symposium served to emphasize what is already well known, namely, that the total number of students undergoing higher education in the U.S.S.R. is very high compared with Great Britain.

Prof. C. F. Powell was elected president of the Federation in succession to Prof. F. Joliot-Curie, and the new vice-presidents are Academician Li Sze-kwang (China), Academician A. I. Oparin (U.S.S.R.), Prof. C. Sadron (France), Dr. G. P. Nørregård (Denmark) and Prof. J. D. Bernal (Great Britain). After the conclusion of the Assembly, all members were invited to go to Leningrad as the guests of the Union of Higher Educational and Scientific Workers of the U.S.S.R. The thirty-three representatives who went to Leningrad were able to make contact with the scientific institutes of the Academy of Sciences and with departments of the University of Leningrad. Visits to places of historic and artistic interest were also arranged.

Geochemistry

A SYMPOSIUM on geochemistry was held in Paris during July 22–24 under the auspices of the International Union of Pure and Applied Chemistry. It was organized by the local chairman, Prof. E. Raguin, and presided over by Prof. T. F. W. Barth with Prof. K. Rankama acting as a secretary. One hundred and fifteen members, representing eighteen countries, were present, and fifty-two papers were read and discussed. The subjects dealt with comprised geochemical aspects of cosmology, distribution of chemical elements, geochemical aspects of rocks and mineral waters, radioactive elements, geochronology, geochemistry of ore deposits and carbonaceous deposits and geochemical prospecting. Prior to the Symposium, on July 20 and 21, eight members of the Commission on Geochemistry met and discussed current business and plans for the future. A joint meeting of the Commission with representatives of the Geochemical Society and the Geochemical Societies of France and Japan was also held.

The present composition of the Commission on Geochemistry is as follows: *President*, T. F. W. Barth (Oslo); *Vice-President*, C. W. Correns (Göttingen); *Secretary*, K. Rankama (Helsinki); *Other Members*, H. S. Brown (Pasadena), C. Burri (Zurich), M. Fleischer (Washington, D.C.), S. I. Tomkeieff (Newcastle upon Tyne), H. C. Urey (Chicago), L. R. Wager (Oxford) and F. E. Wickman (Stockholm); *Previously elected observer*, G. Carobbi (Florence); *Newly elected observers* (pending approval by the Union), L. H. Ahrens (Cape Town), C. G. Du Plessis

(Cape Town), A. B. Edwards (Melbourne), G. E. Hutchinson (New Haven, Conn.), E. Ingerson (Washington, D.C.), J. Orcel (Paris), N. W. Rakestraw (La Jolla, Cal.), C. G. Rossby (Stockholm), W. W. Rubey (Washington, D.C.), H. E. Suess (La Jolla, Cal.), K. Sugawara (Nagoya), H. G. Thode (Hamilton, Ontario), S. Tsuboi (Tokyo), A. P. Vinogradov (Moscow).

Nature Conservation

The sixth technical meeting of the International Union for the Conservation of Nature and Natural Resources was held in Edinburgh during June 20–28. Previous accounts of the meeting have directed attention to the increasing importance of the Union as the 'World Parliament of Nature', the aims of which are to conserve renewable natural resources and areas of outstanding natural interest and to protect flora and fauna having scientific, historic or æsthetic significance (*Nature*, 178, 175; 1956). The Proceedings of the Edinburgh conference have now been published and includes full texts or summaries of most of the papers submitted together with the relevant discussions. To reduce the size of the Proceedings, the Société Nationale d'Acclimatation de France (57 rue Cuvier, Paris, 5e) has published a full account of the papers and discussion relating to the biological consequences of myxomatosis. Copies of the Proceedings may be obtained from the Nature Conservancy, 19 Belgrave Square, London, S.W.1, 25*s*.

Serengeti National Park, Tanganyika

Proposals to partition the Serengeti National Park, Tanganyika, were first published in January 1956. Although these were reluctantly accepted by the Trustees of the Park, they were immediately opposed by the Tanganyika and Kenya wild-life societies, as well as by organizations in other countries. One of these was the Fauna Preservation Society, which later arranged for an ecological survey of the area to be carried out. This has now been done by Prof. W. H. Pearsall; details of his report and recommendations have been accepted by the Society and form the bulk of a recent issue of *Oryx* (4, No. 2; August 1957). Prof. Pearsall recommends that a national park, primarily for game preservation, be maintained in the central and western Serengeti, including the Moru area; that a national park for game, indigenous forest and water conservation be maintained in the Crater Highlands; that a connecting corridor with limited human access will be necessary between Ngorongoro Crater and the central plains, if the Ngorongoro Crater Camp is to be maintained as a tourist attraction; that arrangements be made for the early exclusion of pastoral occupation from the national parks; that systematic attempts be made to develop the Masai-occupied territories, particularly in regard to water (conservation and distribution) and grassland and range management; and that a research unit be set up to study the problems of game and habitat conservation. These recommendations have been submitted by the Society to a committee which has been set up by the Tanganyika Government to consider the Serengeti.

Phytopharmacy

A report has been issued of the eighth Annual Symposium of Phytopharmacy (*Mededelingen van de Landbouwhogeschool en de Opzoekingsstations van de Staat te Gent*, 21, No. 3; 1956. Pp. ii+293–642. Gent: Rijkslandbouwhogeschool, 1956). It contains articles of special interest on insecticides, fungicides, herbicides, nematicides, etc., and related topics, for example, toxicology of organic phosphorus insecticides. There are also contributions on topics of a more general character, for example, the present state of research on fungicides, and a discussion on the postulates, or canons, of Koch in their application to the problems of nematology. The control of insect pests in foodstuffs (for example, oat flakes in packets), by high-frequency electrical fields, is yet another subject on which some interesting and important information has been obtained. This procedure appears to have been successful, the commodity suffering no detectable alteration. The multi-resistance of the common house-fly, induced by selection with insecticides, is described and the probable mechanisms involved discussed in some detail. Several factors which may influence the occurrence of spray damage, that is, after the application of insecticidal or fungicidal sprays, are reviewed, and it is noted that many varieties of fruit trees show very considerable differences in susceptibility during the growing season, and that the greatest damage is sustained during the period of vigorous growth, in particular, immediately after flowering. It has been found that the penetration of a fungicide into a leaf, with consequential damage, may be promoted when the fungicide is mixed with an insecticide in which organic solvents are present. The present status of griseofulvin for the protection of plants has also been considered, the research findings to date being generally, and sometimes very, encouraging.

Sulphonylureas in Experimental and Clinical Diabetes

The sulphonylureas reduce the level of the blood sugar apparently by stimulating the production of insulin by the pancreas. They also increase the effectiveness of injected insulin. These drugs are active when given by mouth and seem to offer the possibility of an alternative to injections of insulin in the treatment of some forms of diabetes mellitus. Control of the diet is still necessary, and some, at any rate, of the derivatives produce harmful side-reactions. In February, the New York Academy of Sciences held a conference on the effects of the sulphonylureas and related compounds in experimental and clinical diabetes (*Annals N.Y. Acad. Sci.*, 71, 1; 1957), during which thirty-two papers were presented. Prof. B. A. Houssay was among the contributors, and the papers dealt both with the scientific and clinical aspects of the action of the drugs.

Properties of Materials at High Rates of Strain

The deformation of solids is a wide and fascinating subject, of interest especially to engineers, metallurgists and physicists. In particular, behaviour when the deformation is rapid is important in various ways. This aspect is being studied in a number of laboratories, and at the suggestion of the Scientific Advisory Council of the Ministry of Supply, the Institution of Mechanical Engineers held in London during April 30–May 2 a conference on "Properties of Materials at High Rates of Strain", which was apparently the first ever held on the subject. A rate of strain greater than about one per second was arbitrarily decided upon as constituting a high rate, but this figure was not intended to be binding. The opening lecture was given by Dr. A. H. Cottrell, who dealt with some fundamental principles. The detailed papers were classified under the following headings: experimental techniques; metal working; impulse loading and stress waves; non-metallic materials; and basic properties. The matter presented forms a comprehensive, useful and interesting account of the subject. Synopses of the papers are given in the programme of the conference, and advance copies of the papers are available from the Institution of Mechanical Engineers. Ultimately, bound and indexed volumes of the proceedings, including the discussions, will be published.

National Museums of Southern Rhodesia

THE annual report for 1956 of the National Museums of Southern Rhodesia (Pp. 21. Bulawayo: National Museums of Southern Rhodesia. n.p.) records that although plans for a new building for the National Museum in Bulawayo were completed during the year, owing to the suggestion that the building would be better sited in North Park, further developments have been suspended while discussions continue. The Trustees favour the North Park site. At Salisbury a new building is urgently required for the Queen Victoria Museum. In the meanwhile, under the new curator, Col. H. L. Boultbee, some of the galleries have been modernized and every effort has been made to gain the interest and support of the public. Certain limitations are imposed by lack of staff and accommodation, but the Museum is compensating for these handicaps by its activities in other directions, such as the formation of the 'Friends of the Museum', a vigorous schools service and lectures by the staff to many cognate organizations.

Commonwealth Fund Fellowships for Advanced Study and Travel in the United States

A NUMBER of Commonwealth Fund Fellowships are again being offered by the Commonwealth Fund, New York, to British subjects for study and travel in the United States. All expenses of study, travel and living will be met, with some adjustment of stipend for married men. The fellowships, which are open to British men or women who have not previously worked for more than a few months in the United States, are in six categories: *General*, twenty fellowships to graduates of a university in Great Britain or Northern Ireland; candidates must be available in London for interview in March 1958; age, 23–32; tenure, 12–21 months; applications by December 16. *Home Civil Service*, five fellowships to permanent members in the higher ranks of the Civil Service in Great Britain, three for the administrative grades and two for the scientific and professional grades; age, preferably less than 40; tenure, 9–15 months; applications by December 10 to the Treasury. *Australian and New Zealand Civil Services*, five fellowships to Civil servants in the Governments of Australia and New Zealand; age, less than 40; tenure, 9–15 months; applications by November 1 to Dr. H. Carlyle Forster, Box 4079, Melbourne, or the Public Service Commission, Wellington, N.Z., respectively. *Oversea Civil Service*, two fellowships to Civil servants in the Governments of British Colonies, Protectorates and Trust Territories; age, less than 40; tenure, 9–15 months; applications by November 17 to the Colonial Office, London. *Journalism*, three fellowships to journalists, practising in the United Kingdom and engaged on the opinion-making of broadly editorial side of their profession; age, 23–35; tenure, 9–15 months; applications by December 31. *American Studies*, four fellowships to faculty members appointed to or holding posts in American studies in universities in the United Kingdom; candidates to be nominated by their universities; tenure, 4–15 months. Application forms and further information may be obtained through British universities or through Government departments, or from The Warden, Harkness House, 35 Portman Square, London, W.1.

The Corday-Morgan Commonwealth Fellowship

THE Chemical Society invites applications from citizens of any country within the British Commonwealth for the Corday-Morgan Commonwealth Fellowship, to be awarded for post-doctorate (or equivalent) study in any branch of chemistry. It will be tenable for one year in some part of the British Commonwealth other than that in which the candidate received his scientific education, at any university, research institution or other place of study approved by the Corday-Morgan Memorial Fund Executive. The value of the Fellowship will be £700 per annum, but additional allowances may be granted in appropriate cases for travel, university fees, etc. The appointment will date from October 1, 1958, or such other date as may be arranged. Application forms may be obtained from the Secretary, Corday-Morgan Memorial Fund Executive, c/o Chemical Society, Burlington House, London, W.1. Applications must be received by the Secretary not later than March 1, 1958.

University News: Bristol

DR. H. G. H. KEARNS, at present reader in entomology in the University, has been appointed director of the Long Ashton Research Station and to a professorship in the University.

Khartoum

THE following appointments have recently been announced: Dr. J. B. Lynch, lecturer in pathology, University of Liverpool, to the chair of pathology; Mr. Donald Portway, lately Master of St. Catharine's College, Cambridge, to the chair of mechanical engineering.

Announcements

PROF. T. A. BENNET-CLARK, professor of botany in the University of London (King's College), and Prof. E. G. COX, professor of inorganic and structural chemistry in the University of Leeds, have been appointed to fill vacancies in the membership of the Agricultural Research Council caused by the retirement of Prof. E. J. Maskell and Prof. L. P. Pugh. Prof. P. B. Medawar has been re-appointed for a further term.

A COURSE of six lectures on "The Technique of Technical Writing" will be given at the Borough Polytechnic, Borough Road, London, S.E.1, on Fridays at 2.30 p.m. beginning on October 11, by G. Parr, technical director of Chapman and Hall, Ltd. The fee for the course is ten shillings. Further details may be obtained from the Secretary of the Polytechnic.

ROYAL GREENWICH OBSERVATORY

REPORT FOR 1956–57

THE annual report of the Astronomer Royal for the period April 1, 1956–March 31, 1957*, includes Greenwich and Abinger, Herstmonceux, and Hartland in the section on "Grounds and Buildings". The grounds and buildings at Greenwich and Abinger have not been completely vacated, and under the section devoted to Herstmonceux it is announced that the equatorial group has not yet been handed over to the Royal Greenwich Observatory, but parts of the telescopes have been installed in certain domes. The aluminizing plant, set up in the equatorial group, has been used satisfactorily. The West Block has not been handed over to the Royal Greenwich Observatory, but by special arrangement quartz clocks have been installed. On October 5, 1956, the buildings of the Royal Greenwich Observatory at Hartland were officially handed over.

The Cooke transit circle has been brought into regular use: an electronic automatic punching chronograph has been made and is ready for installation in the transit circle pavilion. The Yapp 36-in. reflector was dismounted and brought from Greenwich to Herstmonceux, and the polar axis has been erected on site, the remainder of the telescope being in store at Herstmonceux. The mirror, which was refigured and aluminized by Sir Howard Grubb, Parsons and Co., is stored at Herstmonceux. The 30-in. reflector, which was formerly mounted on the axis of the 26-in. refractor, has been refigured by Messrs. Cox, Hargreaves and Thomson and afterwards aluminized at Herstmonceux, and has been erected in Dome *A* in the equatorial group. A new polar axis and fork were made for it by the same firm, and it is now ready for test. The Isaac Roberts reflector, acquired on loan from the Science Museum, has been set up in Dome *C*, and its erection is practically complete. The astrographic refractor, 26-in. refractor and the 28-in. refractor have been dismantled and are in store at Herstmonceux.

In the section on astronomical observations, reference is made to the Cooke reversible transit circle, with which 886 transits have been observed since November 28, and the reductions are complete to February 20. A total of 333 stellar plates, containing the images of four or more stars, together with the associated chronograph plates, were obtained with the photographic zenith tube. All these plates have been measured and the data from the stellar plates have been punched on to Hollerith cards. Photographs of the Sun in white light with the photoheliograph, and in Hα light with the birefringent filter, were taken throughout the year. Solar activity continued to rise steeply until November 1956, when the Zurich sunspot number for the month was as high as that for any month of the previous sunspot cycles. During the year, 118 solar flares were observed at Herstmonceux, which was a little more than in any previous similar period. Ionospheric recordings (atmospherics) showed frequent solar flare sudden enhancements. Ionospheric fade-out effects were shown directly from a Paris transmitter by means of a monitor of signal strength, and the information thus given differed somewhat from that provided by the sudden enhancement record.

The Astrometry Department was transferred to Herstmonceux at the end of May and in the short interval before that five plates of the minor planet Vesta and twelve of other minor planets were obtained. Measurement and reduction of these and earlier plates have continued. Searching tests have been made on plates taken with the 17/24-in. Cambridge Schmidt telescope with the object of determining their suitability for astronomy, and as a result of these it appears that straight Schmidt optics, combined with a suitable mechanical design, might well yield a telescope capable of astrometric use.

Among other branches reference may be made to the Cosmic Ray Department, the equipment for which has been largely completed, and the Department is in full operation. The Electronics Laboratory is now at Herstmonceux, and the department has been augmented by the electronics staff of the Time Department at Abinger, Greenwich and Herstmonceux. At Abinger Magnetic Observatory routine work has been carried on by a junior member, assisted occasionally by senior members of the staff from Herstmonceux, following the retirement of the officer-in-charge and the transfer of two of the staff of the magnetic staff to Hartland. In addition to the routine publications of H.M. Nautical Almanac Office, there has been published a new edition of "Interpolation and Allied Tables", the general scope of which is similar to the original edition of 1936, but it has been greatly expanded in content, and in three months 2,000 copies were sold—an indication of the needs that it fills. The Office still continues its work for the Hydrographic Department, that is, the calculation of the data required for the plotting on charts of the Decca navigational lattices. The astrograph, which is designed to simplify astronomical navigation in the air by the projection of precalculated star curves, is being brought back into service, and the Office has calculated new curves for a conventional astrograph and also for an experimental modified model of its own design. As mentioned in the previous year's report, the Office has been investigating the accuracy of astronomical observation at sea, and the overall probable error of a position line turns out to be about 0·8′, but the distribution of error is far from Gaussian, with a preponderance of large values. The most significant feature about the observations is their poor quality; the proportion of 'blunders' is high and the observations from nearly 10 per cent of the observers could not be used.

At the end of the Report there is a short note on the Isaac Newton telescope: so much progress has been made by the Executive Committee towards the production of a design for the telescope that a specification was approved by this Committee and submitted to a firm of instrument makers. Financial approval for placing a specific contract is now being sought.

COLONIAL DEVELOPMENT AND WELFARE SCHEMES

REPORT FOR 1956–57

THE schemes made under the Colonial Development and Welfare Acts in the period April 1, 1956–March 31, 1957, which are detailed in the latest return*, bring the total commitments for development and welfare under those Acts to £170,452,589, and for research schemes to £16,874,215, of which £23,755,193 and £2,202,880, respectively, are for the year in question. Of this last, £943,301 is for agriculture, £529,979 for medicine, £199,683 for tsetse and trypanosomiasis, £171,128 for insecticides, £103,085 for fisheries, £87,796 for products research, £14,982 for social science, £59,350 for locust control and £10,550 for economics research.

Of the actual research schemes, £166,744 is for the East African Veterinary Research Organization, £229,600 for the East African Agriculture and Forestry Research Organization, £147,229 for the West African Council for Medical Research, £65,169 for the East African Medical Survey and Research Institute, £96,300 for the East African Virus Research Institute, £36,346 for the East African Marine Fisheries Research Organization, £36,711 for the East African Inland Fisheries Research Organization and £28,775 for the East African Institute of Malaria and Vector-Borne Diseases, all for the period 1956–60. The West African Institute for Trypanosomiasis Research received a supplementary £119,050, the Organization for Agricultural Research and Land Use Planning, Tanganyika, £99,616, the East African Trypanosomiasis Research Organization £68,174, the Colonial Pesticides Research Unit, East Africa, £97,150, the Colonial Microbiological Research Institute, Trinidad, £50,104, research into natural products of medical interest at the University College of the West Indies, £33,700, the establishment of a Soils Laboratory, Sarawak, £21,000, physiological and biochemical research in East Africa, £26,478, and research on cotton pests in Nyasaland, £14,487. Agricultural research services in Northern Rhodesia received £52,400 for 1956–58, £41,823 was provided for maintenance of the Colonial Section, Building Research Station (Department of Scientific and Industrial Research), and £15,308 for fundamental insecticides research at the Silwood Park Field Station of the Imperial College of Science and Technology. For the period 1956–60, £18,914 was provided to augment the staff at the Long Ashton Research Station; £79,473 for the Agricultural Research and Experimental Station, Lilongwe, Nyasaland; £60,000 to maintain the Medical Research Council's Field Station, Fajara, Gambia; £40,815 for the agricultural research section of the Abyan Development Programme, Aden; £50,500 for maintenance of the Experimental Rice Station, Federation of Malaya; and £30,550 for maintenance of the Livestock Experimental Station, Ebini, British Guiana.

The development and welfare schemes include a number of large schemes for the development of roads; for example, £1,800,000 for trunk roads in Nigeria, and £3,450,000 for the development of class *B* trunk roads in the Northern Region there, £486,080 for road construction and improvements in North Borneo, and £297,750 for road construction in Fiji; and also for the development of water supplies, such as £1,300,000 for rural water supplies in Northern Nigeria and £100,000 for minor water supplies in rural areas in Jamaica. Major schemes of particular scientific interest include besides a further £555,000 for the central organization for the Colonial Geodetic and Topographical Survey, and £101,500 for the Central Directorate, Colonial Geological Surveys, £108,840 for the geological survey in the Bechuanaland Protectorate, £359,385 for expansion of the geological survey, British Guiana, and £115,180 for the geological survey, Jamaica, £294,750 for cacao expansion, Jamaica, £1,200,000 for African agricultural development in Kenya, £56,550 for leprosy control in Eastern Nigeria, and £120,000 for agricultural research and land use planning, Tanganyika. Among many schemes for educational development may be mentioned the £190,000 for a new hall of residence, £125,850 for senior staff housing, and £111,800 for extensions to the medical school, all at the University College of East Africa; £100,000 for the men's hall of residence and subordinate staff quarters, Royal Technical College, Nairobi; a further £168,000 for permanent buildings and equipment for the University College of Rhodesia and Nyasaland; a supplementary £516,000 for permanent buildings for the University of Malaya; and, to the University College of the West Indies and the associated teaching hospital, £205,255 for a fourth hall of residence, £137,500 for extension of science schools, and £100,000 for staff houses.

BRITISH NATIONAL FOOD SURVEY

THE preface of the sixth annual report of the National Food Survey Committee, which has recently been published*, states that the series "was introduced in 1950 with the object of providing continuous information on the trends of domestic food consumption, expenditure and nutrition in Great Britain". A few minor modifications in technique have been made in the course of the six years but, broadly, the recording and the analysis follow the same pattern and involve visits to about twenty thousand homes (20,400 in 1954; 18,580 in 1955) and the analysis of more than ten thousand completed records. The cost of the survey in both time and money must be very considerable and it seems pertinent to ask if the results are commensurate in value with the outlay.

Any government interested in maintaining the health of the people at a high level must seek to prevent the occurrence of malnutrition even in the mildest degree, and to do this requires to know the composition of the diet currently consumed. The Survey reports are not published until some eighteen months after the end of the year in which the data are collected, but it may be that the results are available to the Ministry itself in time for action to be taken if any marked fall in nutritive value of the diets should become apparent. If this is not so, the most valuable aspect of the survey—that of giving warning of 'incipient malnutrition'—is being entirely lost. If the survey is being used for this purpose, the next important question is how much reliance can be placed upon the evidence so provided.

---

* Ministry of Agriculture, Fisheries and Food. Domestic Food Consumption and Expenditure 1955: Annual Report of the National Food Survey Committee. Pp. iv+148. (London: H.M. Stationery Office, 1957.) 6s. 6d. net.

The report states that "in 1955 no sub-group fell below 95 per cent (of the estimated requirements) in energy value, but percentages less than 95 were recorded in certain sub-groups for protein, calcium, iron and riboflavin". As the figures represent averages for groups of families, it must be supposed that some families within the groups had intakes considerably below the average 95 per cent. Did such families show any evidence of a deficiency of these particular nutrients? This is apparently not known. For young childless couples in the highest income group the energy value of the recorded diet was 143 per cent and the protein content 150 per cent of the recommended allowances; fat intakes were of the order of 150 grams per head per day. Are these people suffering from their over-indulgence, or should these levels be taken as evidence of incipient malnutrition? At the moment, no one seems to know. For the whole ten thousand families, the caloric value of the diet averaged 105 per cent of the estimated requirement. If food intakes are regularly greater than requirements, body-weights in Great Britain should be steadily increasing. If they are not doing so, then either the estimate of requirements is too low or the assessment of the diet is inaccurate.

It is sometimes forgotten that these records deal only with the quantities of food bought for domestic consumption in the course of the survey week; they do not set out to measure the actual quantity of food eaten by the families concerned. In attempting to assess the adequacy of the diets, arbitrary allowances are made for preparation waste, and a round ten per cent deduction is made for edible material discarded or given to pet animals; meals out are given a 'points' value of breakfast 4, dinner 5, tea 3, and supper 2. It is unlikely that these 'corrections' are equally suitable for all families, all seasons, and all geographical areas. No attempt is made to allow for sweets, alcoholic or soft drinks, ice-creams, etc., nor are changes in larder stocks recorded—as they were when the survey first began. The arbitrary allowances made for cooking losses of thiamine and ascorbic acid, and the low vitamin A value assigned to carotene-rich foods are 'corrections' of questionable value. In all, there is room for a quite considerable degree of error when the analysis is confined to small sub-groups, though the broad general picture obtained may be true enough.

The yardstick against which the recorded diets are measured for adequacy is the set of allowances recommended by a Committee of the British Medical Association in 1950[1]; but in making these recommendations the Committee continually reiterated the 'urgent need' for further extensive study of human nutritional requirements. The failure to parallel the Food Survey with a clinical survey to assess the nutritional state of the consumers of diets of different level means that a most valuable opportunity to forward our knowledge of dietary needs is being entirely missed. As it stands, the Survey provides a mass of interesting detail on price trends, dietary patterns, seasonal, occupational and geographical influences, the effect of family size within different income groups, etc.; but it fails to make any contribution to the knowledge most urgently needed, which relates to what type of diet is best and to what the range of nutrient intake is within which good health can be maintained.

At any time, a food consumption study is of little practical value unless it is made in conjunction with a study of the resultant health of the consumers; at the present time, when such fundamental changes are being introduced into the methods of producing and processing our everyday foods, this second study is of paramount importance and it is to be hoped that future reports will include a section on the nutritional state of the families eating the diets described in so much detail.

M. W. Grant

[1] Report of the Committee on Nutrition. British Medical Association (1950).

RESEARCH ON ROADS IN BRITAIN

The annual reports of the Road Research Board of the Department of Scientific and Industrial Research and the Director of Road Research for the year 1956 have now appeared*.

The report of the Road Research Board directs attention to the growing road traffic problem and states that a method of evaluating road projects in relation to their economic advantages is to be tried. The importance of training road engineers in traffic engineering and the value of 'before and after' studies with the current road-building programme are emphasized. It is believed that the economic advantages of building new roads have been grossly under-estimated hitherto.

It is suggested that improvement of the facilities for studying the causes and means of reducing accidents is urgent. Closer attention should be paid to the contribution of high speed to the increase in road casualties, because "it may well be that neither the skill of the average driver nor the care normally bestowed on the maintenance of cars is commensurate with their high performance".

The report of the Director of Road Research summarizes the activities of the Road Research Laboratory during 1956; these come mainly under three headings: safety, traffic and materials and methods of construction.

Work on road safety has included tests and recommendations on protective helmets for motor-cyclists. Accident studies have been made with the object of designing safety devices for vehicles, such as interior padding and safety belts. The contribution of the nature of road surfaces to skidding accidents has been investigated; it is estimated that the reduction of accidents due to treating road surfaces at dangerous sites represents a saving of ten times the cost of maintaining the surface with a high resistance to skidding. Statistics of accidents due to various causes have been compiled and are summarized in the report. Vehicle- and road-lighting studies have been made with the object of finding economical methods of reducing accidents due to conditions of night driving.

Traffic statistics are being compiled annually, and detailed surveys of traffic in selected areas are made.

---

* Road Research 1956: The Report of the Road Research Board with the Report of the Director of Road Research. Pp. iv+88+8 plates. (H.M. Stationery Office, London, 1957.) 5s. 6d. net.

Statistics indicate that in rural areas the average speed of traffic is increasing annually by approximately 1 m.p.h., and during 1956 the average speed of private motor-cars under normal conditions was between 45 and 50 m.p.h., goods vehicles being some 5–10 m.p.h. slower. Economic studies of road improvements are an important feature of the work of the laboratory on the traffic problem.

The section on materials and methods of construction contains accounts of experiments on alternative types of road construction, including foundation aspects such as soil moisture and drainage, soil compaction and soil stabilization. Experiments on concrete have been carried out in connexion with the behaviour of high-strength road surfaces: the mechanism of the cracking of concrete and means of achieving a reduced modulus of elasticity without reduced strength, to lessen the liability to cracking, have been investigated. The use of prestressed concrete for road construction has also been investigated. For this to be feasible, the friction between the foundations and the necessarily long concrete slabs must be such that stresses due to thermal effects are not excessive; the difficulty of achieving this has not yet been overcome. Investigations into the properties and behaviour of bituminous road materials have been carried out with particular reference to anti-skid properties and durability.

Miscellaneous investigations have included the use of radioactive techniques for measuring the density of concrete slabs and the moisture content of soil *in situ*.

Salient features of some full-scale road experiments are given in an appendix. T. M. CHARLTON

A SOLAR 'BLOW-OFF' PROMINENCE

THE solar 'blow-off' prominence of May 18, 1956, and its possible effects are described by Dr. M. A. Ellison in two recent papers (*Mon. Not. Roy. Astro. Soc.*, 116, 6; 1956, and *The Observatory*, 77, 896; 1957). This prominence was one of a number generated during February–April 1956 in the highly active centres of the northern solar hemisphere, and it had been followed across the Sun's disk as a typical quiescent dark filament before it blew-off at the west limb on May 18. The observations relating to this blow-off prominence were made with the combined spectrohelioscope and spectrograph and are discussed in the *Monthly Notices*. A height diagram plotted from measurements made at Edinburgh and Meudon (the latter were supplied by L. d'Azambuja from spectroheliograms) shows the rapid outward acceleration, and before 15h. 00m. the outward velocity along the solar radius was 20 km./sec.; after 16h. 07m. it exceeded 600 km./sec. Calibrated plates of the Hα line were taken at 16h. 01m. and 16h. 04m. with the slit of the spectrograph crossing the arch at a mean height of 88×10^3 km. above the limb. The plates were calibrated immediately afterwards in the spectral light from the centre of the solar disk, thus providing means of deducing the Hα brightness of the various points of the prominence which were traversed by the slit. These are tabulated as fractions of the centre of the disk continuum at a wave-length 15 A. outside the Fraunhofer Hα line. The Doppler shifts on these plates gave components of velocity in the line of sight ranging between − 120 km./sec. in the northern leg and + 360 km./sec. in the southern leg.

Among other points dealt with in the paper, reference may be made to the study of the profiles of the Balmer lines at Edinburgh, which indicated a kinetic temperature for the filaments of 10,000°–15,000° K., and are consequently cool regions embedded in the corona itself at a temperature of 10^6 °K. It has been suggested by F. Hoyle that the higher density and lower temperature in the filaments are maintained by a local magnetic field, which compresses the hot material and cools it sufficiently for the hydrogen atoms to radiate in the Balmer lines. If this occurs, then there must be a great release of magnetic energy during the 2-hr. blow-off phase, and it is extremely improbable that the same material which has blown away into space should return precisely to its original site. In conclusion, Dr. Ellison suggests that such high-speed projection of prominence material may well be associated with the generation of radio-waves of frequencies appropriate to the various levels. There is also the possibility of geomagnetic effects occurring on the Earth after a suitable travel-time in those cases where the blow-off occurs near the centre of the solar disk. It is therefore desirable that all blow-off filaments should be recorded and classified at solar observatories during the International Geophysical Year. A simple scheme of classification has been proposed by Ohman, for inclusion in the Geophysical Year *Solar Patrol Forms*, and the hope is expressed that this classification will be generally adopted.

BROOKHAVEN NATIONAL LABORATORY

THE Brookhaven National Laboratory, which is located at Upton, Long Island, about seventy miles east of New York City, was established in 1947 and is operated by a private institution, Associated Universities, Inc., under contract with the United States Atomic Energy Commission. The board of trustees comprises one scientist and one administrator from each of the nine sponsoring universities—Columbia, Cornell, Harvard, Johns Hopkins, Massachusetts Institute of Technology, Princeton, Pennsylvania, Rochester and Yale. The director of the Laboratory is Dr. L. J. Haworth. The issue of *Atoms for Peace Digest* for June 15 (3, No. 1; 1957), the first of several numbers to be devoted to the description of the large American atomic research centres, deals with the work of Brookhaven National Laboratory. Later issues will deal with Oak Ridge, Argonne, and the smaller research establishments of the U.S. Atomic Energy Commission.

Research and development work at Brookhaven is carried out by eight major scientific departments, including the departments of physics, chemistry and biology and medicine. The cosmotron department is now operating the 'Cosmotron' particle accelerator in three shifts, five days a week, and the main study is that of the unstable particles, including heavy mesons and hyperons. An efficient method for the extraction from the 'Cosmotron' of an intense proton beam and its direction on to a liquid-hydrogen target placed outside the accelerator has been developed. The construction of a proton synchrotron was commenced in 1954; it will consist of a steel and copper hoop, 842 ft. in diameter, and will use the new 'strong focusing' principle of accelerator design to accelerate protons to energies of 25,000 MeV. The Brookhaven research reactor, completed in 1950, operates at 30 megawatts, and is a natural uranium, graphite-moderated, air-cooled reactor. It is used for many types of experiments in nuclear research, including a large number of simultaneous experiments involving neutrons and also for the production of radioisotopes. The nuclear engineering department is continuing to contribute to the general development of a liquid-metal fuel reactor and is collaborating closely with Messrs. Babcock and Wilcox, who are responsible for the engineering aspects of the design, fabrication and operation of a liquid-fuel reactor experiment for the U.S. Atomic Energy Commission. The experiment is based on research work done at the Laboratory on the concept of a reactor using uranium fuel dissolved in molten bismuth.

Brookhaven was the first institution in the United States to establish a hospital devoted primarily to research in the use of atomic energy for the diagnosis and treatment of disease. The hospital has 115 beds and treats 'terminal cases', that is, persons suffering from an incurable disease, usually some form of cancer. A new Medical Research Centre is being built which will house a forty-eight-bed research hospital, an industrial medical branch and research departments in medical physics, pathology, microbiology, biochemistry and physiology. The Centre will have the first nuclear reactor designed specifically for medical research and therapy and will be capable of producing a beam of neutrons about fifty times as powerful as the beam from Brookhaven's present general research reactor.

PASTEUR INSTITUTE OF SOUTHERN INDIA

THE brilliant research of Louis Pasteur in the 1880–90 decade not only established bacteriology as a science but also revolutionized the practice of medicine by the introduction of therapeutically and often dramatically effective sera and vaccines. Public recognition of the value to humanity of this new science led to the establishment of, in the words of Pasteur, "those sacred dwellings meaningly described as *laboratories*" through funds provided by, to use the modern idiom, voluntary agencies. To quote the names of a few such laboratories of world-wide repute is to put into perspective the Pasteur Institute of Southern India, this year celebrating the golden jubilee of its foundation in 1907; Pasteur Institute of Paris, founded in 1890; Institute of Infective Diseases in Berlin (1891); Lister Institute of London (1891); Rockefeller Institute for Medical Research of New York (1901); Haffkine Institute of Bombay (1896); Pasteur Institute at Kasauli, India (1900). The scientific achievements of the Pasteur Institute of Southern India, so delightfully situated in the Nilgiri Hills at Coonoor, were acclaimed in 1952 by its selection as the venue for the World Health Organization Rabies Conference.

In his foreword to a souvenir volume issued to mark the golden jubilee* the present director, Dr. N. Veeraraghavan, pays tribute to the distinguished men who have guided the destinies of the Institute and to the workers to whose unremitting endeavours it owes its position in the scientific world to-day. The directors were: Lieut.-Col. J. W. Cornwall, 1907–26; Lieut.-Col. T. H. Gloster, 1926–28; Lieut.-Col. K. R. K. Iyengar, 1928–38 and 1941–46; Major H. W. Mulligan, 1938–41; Lieut.-Col. M. L. Ahuja, 1946–47. At its inception, the Institute was a non-governmental organization managed by a committee on which a wide variety of interests were represented. The objectives were to make available effective means of preventing the occurrence of rabies, to spread the knowledge of such means among the public and to undertake research work on rabies or any other disease in so far as funds and the qualifications of the staff permitted. Changes in vaccine for rabies and methods of production over the years are briefly described, and especial reference is made to the painstaking record-keeping, instituted by Cornwall and still maintained, of the history of hundreds of patients bitten by rabid animals, but untreated, considered in parallel with the results of treatment of persons bitten by the same animals; this continued investigation is considered to be a unique record. In recent years the present director has tested the effect of hyperimmune antirabies serum, as well as a host of drugs claimed to be of therapeutic value in established cases of hydrophobia.

Among many other subjects of research at the Institute have been the entomological studies of Patton about 1920 which culminated in his well-known two-volume text-book; Iyengar's interest in clinical laboratory practice, which led to the creation of a separate department; Mulligan's preoccupation with problems of immunity in malaria and with protozoon parasites generally; Ahuja's heed for the potency of vaccines and his association with the action of heparin on Russell's viper venom.

The potential for research and expansion available at the Institute to-day is in large measure due to the scientific ability, administrative capacity, sterling character and vision of Col. Cornwall during his twenty years of service as director. To-day the Institute's laboratories co-operate with the World Health Organization in their world-wide studies on rabies, *Q*-fever and international interlaboratory testing of freeze-dried sera from syphilitic and non-syphilitic sources. Dr. I. G. K. Menon, assistant director, is a member of the World Health Organization expert advisory panel on virus diseases and has instituted new inquiries on the respiratory group of viruses, the intestinal group of viruses and on the recombination and mutations phenomena in influenza viruses.

A section of the souvenir volume describes briefly the scientific contributions by the Institute during fifty years on the following subjects: rabies, influenza, *Q*-fever, cholera, typhoid fever, diphtheria, fusospirochætosis, serology of syphilis, tropical eosinophilia, malaria, leishmaniasis, venoms and entomology. The last section is the Scientific Report of the Institute for the year 1956 and includes an experimental evaluation of recent advances in anti-rabies treatment, an assessment of the value of 5 per cent simple vaccine in human treatment and studies on the cultivation of the rabies virus *in vitro*.

SOIL MICROBIOLOGY

ANY further advance in our knowledge of the biological events which occur in soil depends upon the development of new techniques to study the activities of soil organisms in various ecological situations. In consequence, a symposium on "Methods of Studying the Microbiology of Soils" was held under the direction of Prof. Paul Simonart at the University Institute of Agronomy, Louvain, Belgium, during June 3–5. The meeting was attended by thirty-nine participants from twelve European countries and was the result of a proposal by Commission III (Soil Biology) made at the Sixth International Congress of Soil Science in Paris, 1956. Each session began with a review of one aspect of the sampling of specific groups of organisms and the determination of their activities in soil, and concluded with detailed discussion of the points raised by the reviewer. The reviewers presented personal views as well as those included in contributions that had been circulated to all participants before the symposium.

In his opening address to the symposium, Prof. Simonart (who took the chair at the first session) welcomed the participants, and then went on to stress the importance of micro-organisms in the maintenance of life on earth. He described the intense interest that was aroused among earlier investigators by the then unique biochemical transformations such as nitrogen fixation and nitrification which certain soil bacteria can bring about. In conclusion, he pointed out that heterotrophic soil microbes are now receiving more attention than they did in the past.

The review paper by Mme. J. Ziemieka (Pulawy, Poland) described how variations in sampling procedure can influence the results of surveys of soil micro-organisms. Mme. J. Golebiowska *et al.* (Pulawy) had made an investigation of the sources of variability of counts of micro-organisms obtained by the dilution plate technique when the plates had been prepared from samples of soil which had received various treatments. The results showed that the number of microbes in soil samples decreased with the duration of the storage period. Variations in treatment had very little influence on the population levels of soils stored for periods of more than one month in either dry or humid conditions or sifted either before or after the storage period. Counts of micro-organisms varied considerably between samples taken from different positions in one field, whereas the variation exhibited by samples taken from the same place at different times of the year was considerably less. It was suggested that soil samples should be investigated immediately after their removal from the field or after storage for a fortnight. Prof. Simonart and Dr. R. Willeman had determined the influence of desiccation on counts of soil bacteria and showed that the moisture content of samples from a waterlogged soil and stored in varying humidity regimes had a considerable influence on counts of bacterial colonies. Counts fell with decreasing moisture content especially when the moisture content was lowered from 100 to 80 per cent saturation, when they fell one thousandfold. Dr. W. G. Harmsen (Groningen) described how the use of a ball mill to homogenize soil samples before the preparation of dilutions gives an increase in the bacterial count because of fragmentation of bacterial colonies but a reduction in the fungal count because of damage to mycelia.

Prof. V. Treccani (Milan) presided at the second session, which began with a general outline given by Prof. E. N. Michoustine (Academy of Sciences, Moscow) of the various methods employed in the U.S.S.R. for determining the biological activity of soils. The potential fertility and classification of Russian soils are assessed with the aid of microbiological analyses. A useful index of potential fertility has been the determination of the ratio of the numbers of soil bacteria which are able to utilize inorganic nitrogen to those which use organic nitrogen as a nitrogen source. Results show that the proportion of soil bacteria which develop on media containing inorganic nitrogen increases with the fertility of the soil. It has also been found that tillage brings about an increase in the proportion of soil bacilli in the total microbial population and that these bacteria are more abundant in warm soils than cold. Drs. A. V. Rybalkina and E. V. Kononenko (U.S.S.R.) described a method to assess the total activity of the soil microflora, in which glass slides covered with thin films of sterile nutrient agar were buried in soil. Prof. A. Imsenecki (Academy of Sciences, Moscow) showed how the elective culture technique has been useful for the isolation of bacteria with specialized nutritional requirements, but its usefulness suffers from several defects and the results are often difficult to interpret. Prof. N. A. Krassilnikov (U.S.S.R.) submitted an account of the microhabitat of species of *Azotobacter* in the soil and rhizosphere, describing also the natural distribution of genetic strains in the soil. An account of the mobilization by micro-organisms of phosphorus contained in certain water-insoluble minerals and the effect of the activity of these organisms on plant growth was given by Dr. G. Laslo (Agricultural Research Institute, Bucharest).

The third session, with Dr. Harmsen in the chair, was devoted to a discussion of methods of counting soil bacteria. Dr. J. Pochon gave a comprehensive review of work carried out at the Department of Soil Microbiology at the Pasteur Institute which has brought about improvements in the methodology of sampling soil bacteria. The microscopic examination of soil suspensions to estimate the total bacterial count has shown that only 1–10 per cent of the organisms counted in soil suspensions develop on counting plates. Drs. J. Augier and J. Pochon have examined the main defects of counting by direct microscopy, among which are the inability of the observer to distinguish with any degree of confidence dead from living bacteria and small inert particles from bacteria. They have made use of the fact that living cells absorb the dye acridine orange and fluoresce green, whereas dead cells and organic matter fluoresce red or red-brown. Soil suspensions prepared with distilled water are generally heterogeneous, but homogeneous suspensions can be obtained by using a 0·1 per cent solution of the dispersing agent sodium pyrophosphate. The choice of medium employed in making the total counts of soil bacteria has to be arbitrary, but Dr. M. A. Chalvignac found that physiological groups isolated by media containing aqueous extracts of soil include ammonifying, denitrifying, proteolytic and amylolytic bacteria. The proportions of these forms isolated by soil extracts were similar to the relative numbers of the different physiological groups isolated by selective media. Dr. Pochon described different aspects of the use of a quantitative method of measuring the activity of physiological groups of aerobic and anaerobic micro-organisms. Liquid media containing test substrates are dispensed into tubes to which are added a known series of soil dilutions and then incubated (Dr. J. Pochon *et al.*). The tubes are examined daily for the disappearance of the substrate and for the appearance of metabolites. An example of a precise test for cellulolytic activity employing a suspension of cellulose fibres as a test substrate was given by Dr. H. de Barjac. The results can be expressed as the number of organisms per gram of soil or graphically as an activity curve (Dr. D. Lavergne) by employing a new method of calculating results of dilution tube analyses (Drs. J. Augier and D. Lavergne). Thermophilic bacteria are not very abundant in soil, but besides cellulolytic forms, amylolytic, denitrifying and sulphate-reducing thermophils can be isolated from the soil by variations of the dilution tube technique (Dr. J. Lajudie).

Methods of sampling soil fungi were discussed in the penultimate session, which was presided over by J. S. Waid (Nature Conservancy, Great Britain) and began with a paper given by Prof. Simonart, written in collaboration with Prof. O. Verona (Pisa). The review described the important part that fungi play in the carbon and nitrogen cycles and in plant nutrition even though their biochemical activities as a group are more restricted than those of the bacteria. Soil fungi are difficult to count because of their filamentous habit of growth, and during the preparation of soil suspensions mycelia fragment and colony structure are lost. Fungal colonies which develop on sampling plates may have arisen either from active hyphæ or from inactive propagules. Even though many groups of fungi are known to be active in the soil, for example, Basidiomycetes, they may never be seen on isolation plates because they are not selected by the conditions of isolation and culture. Another difficulty is to find a suitable means of expressing fungal activity which truly reflects events which occur in the soil.

J. S. Waid and M. J. Woodman submitted a method of estimating hyphal activity which partially overcomes some of the defects of the Rossi–Cholodny contact slide method. In place of glass slides, nylon gauze is buried in soil and left for several months. Fungal activity is estimated by counting the number of hyphæ per mesh, and the technique reveals differences in activity in contrasting soil types. Dr. D. Parkinson (University of Liverpool) described new methods for the qualitative and quantitative study of fungi in the rhizosphere. A soil box technique has been devised to isolate mycelia active in the rhizosphere of various parts of a root system. A direct method can also be employed to estimate the amount of fungal development in the rhizosphere by preparing slides by a soil impression technique. The results demonstrate the existence of well-defined microfloras in various parts of the rhizosphere at different stages of plant development. A paper by J. S. Waid, C. K. Capstick and D. C. Twinn argued that fungal infections of free-living nematodes can only be accurately estimated with efficient methods of sampling soil nematodes. Using a method with an extraction-rate of 97 per cent it was found that 45 per cent of a sample of nematodes was infected by either saprophytic or predacious fungi, but it is not known how many of the infected nematodes were dead at the time of sampling.

During the final session, which was presided over by Dr. J. Duche (Gif-sur-Yvette, France), the possibility of developing standard methods for sampling soil micro-organisms was criticized by Dr. T. K. Wieringa (Wageningen). While agreeing that microbial, chemical and physical analyses are complementary when determining the economic potentialities of soils, Dr. Wieringa emphasized that the characterization of soils by routine microbiological methods is laborious and limited by practical considerations. He described various ways of measuring soil activity which had not been considered in detail by the symposium, such as the measurement of carbon dioxide production, carbohydrate decomposition, the measurement of mineral deficiencies with microbial growth assays and the effect of adding various substrates to soils such as urea or glutamine.

During the discussion of Dr. Wieringa's paper several participants stated that it is nearly impossible to obtain uniform counts of soil micro-organisms from one sample analysed by separate laboratories, and this fact makes the biological characterization of soils difficult. Dr. Pochon then proposed a scheme by which all participants of the symposium were invited to take part in carrying out a limited number of microbiological analyses and tests of biological activity upon two soil types bearing characteristic vegetation. The results obtained from widely scattered laboratories could then be compared to determine if soils could be characterized by a standard microbiological procedure.

It is a pleasure to record the excellence of the organization and arrangements for the symposium made by the University of Louvain and the International Society of Soil Science. The success of the meeting was due to the good humour, patience and hospitality of Prof. Simonart and his colleagues, under whose supervision the full proceedings of the symposium are now being prepared for publication.

D. PARKINSON

BIOLOGY OF HAIR GROWTH

A SYMPOSIUM on the biology of hair growth, organized by Prof. W. Montagna (Providence) and Prof. W. S. Bullough (Birkbeck College, London) under the auspices of the British Society for Research on Ageing, was held in London at the Royal College of Surgeons during August 7–9. The symposium secretary was Dr. G. Bourne (St. Bartholomew's Hospital Medical College, London). The very large audience from Europe and the United States was welcomed by Sir Francis Fraser (British Postgraduate Medical Federation, London), and introductory addresses were also given by Prof. Montagna and Prof. S. Rothman (Chicago), who both referred to the great advances made during the past decade in our knowledge of the structure and physiology of mammalian skin.

The first day was devoted to the structure of the hair and the hair follicle. In the opening address Dr. E. Van Scott (Betheeda) dealt with the anatomy of the human hair follicle, describing in particular the changes which occur with age. He was followed by

Prof. Montagna, who discussed the manner in which the undifferentiated matrix cells move upwards to arrange themselves in concentric sheaths prior to their differentiation. Of particular interest was his account of the follicular blood system, and of the way in which it is turned inside out as the follicle passes from anagen to catagen. Dr. O. Braun-Falco (Mainz) then described the distribution of enzyme systems as revealed by histochemical techniques, stressing among other things the evident importance of Krebs cycle and cytochrome enzymes in the active matrix. In the discussion following these papers attention was directed to what proved to be two of the recurrent themes of the symposium, the role of the dermal papilla and the nature of the drastic change in the matrix cells during the onset of anagen. It was suggested by several speakers that these two are probably closely interrelated, the initial stimulus to the growth of a new hair developing in the dermal papilla and spreading from there to the matrix cells. Evidently the dermal papilla contains active enzyme systems during the follicular growth phase, but there is an apparent lack of activity during the follicular resting phase.

The account of follicular structure was continued by Dr. E. H. Mercer (London). With the use of a new embedding medium which allowed excellent sections to be cut at extreme thinness, he was able to show a beautiful series of photographs taken with an electron microscope. He first examined the structure of the undifferentiated matrix cells and the irregular nature of their boundary with the dermal papilla. He then gave details of the intracellular formation of keratin fibrils in those cells destined to form the hair shaft, and showed how such fibrils ultimately filled the dying cells. Those cells destined to be part of the inner root sheath first lay down trichohyaline granules which apparently join together and become fibrous in the region where the sheath itself becomes birefringent. In the more static cells of the outer root sheath the cell membranes were shown to be highly folded. Later discussion ranged over the question as to how far the details described might be artefacts due to the drastic nature of the technique, but Dr. Mercer was confident that his results were reasonably accurate. The day then ended with a detailed account by Dr. G. Matoltsy (New York) of the chemistry of the keratinization of skin, horn, and especially hair.

The second day began with a description by Dr. E. H. Mercer of the biosynthesis of fibres. This was an especially interesting contribution, in that comparisons were made with such other forms of fibre formation as are seen in collagen, in the silk glands of caterpillars, and in the egg-capsule glands of cockroaches. He traced fibre formation from the amino-acid micromolecules, through the precursor macromolecules to the fibrillar macromolecules and the stabilized intracellular aggregations of fibrils. He discussed the alternative possibilities that in fibril formation the polypeptide chains of the precursor macromolecules may open out, or that these macromolecular blocks may fuse together end to end. On the latter alternative, if the blocks are symmetrical a straight fibril should result, but if they are asymmetrical the result should be a helix. After this address, Dr. T. Fitzpatrick (Portland, Oregon) considered the nature of hair pigments. He pointed out that they fall into two chemical groups, the brown-black melanin pigments which are so widespread in Nature and the yellow-red pheomelanin pigments. These two pigment groups are under separate genetic control, and the two metabolic pathways and their interconnexions were described in detail.

Dr. H. Chase (Providence) returned to the question of the various sheaths of cells which form the hair and the inner root sheath. He stressed again the precise way in which the undifferentiated matrix cells orient themselves to form these sheaths, and described elegant experiments by which the matrix cells could be displaced. In those follicles which survived this drastic treatment it was found that the displacement of the matrix cells in no way affected the subsequent formation of the hair, thus showing that the cells are equipotent and that their subsequent differentiation is entirely dependent on the position in which they find themselves. Dr. Chase also introduced the subject of the behaviour of the pigment cells, and this was taken up in more detail in the subsequent paper by Dr. M. S. C. Birbeck (London). Using electron microscopy, he described the structure of the melanocytes on the top of the dermal papilla, gave details of the formation of melanin granules in association with intracellular cytoplasmic lamellæ, and showed how the granules are passed through the cell wall into the adjacent pre-cortical cells.

The attention of the symposium then turned to the physiological aspects of hair formation. Prof. A. Durward (Leeds) began with a stimulating account of the vascularization of follicles. The smaller follicles have no particular blood supply, and capillaries do not even penetrate into the dermal papillæ. The larger follicles, however, are intimately surrounded by a capillary network and their dermal papillæ are well vascularized. In the rat the production of new hairs occurs in waves passing ventrodorsally, and the blood flow was shown to be augmented in regions of rapid hair growth. The paper ended with a consideration of the effects of plucking quiescent hairs. Such treatment activates the follicles, increases the blood flow, and results in the production of new hairs. However, this only happens if a large enough area of hair is plucked, a result which suggests that the plucking of only a few follicles results in too small a stimulus.

The second day ended with a paper by Prof. W. S. Bullough and Dr. Edna B. Laurence (Birkbeck College, London) on the mitotic activity of the follicle. They began with a description of the mitotic pattern in the growing follicle, and of the remarkably high rate of mitosis of the matrix cells. The energy relations of this great mitotic activity were then described, and it was shown by means of *in vitro* studies that cell division is completely dependent on respiration and that it cannot be supported by glycolysis alone. The two most important raw materials are glucose and oxygen and any inhibitor of glycolysis, the Krebs cycle, the cytochrome system, or the processes of energy transfer immediately inhibits mitosis. In the intact mouse the active mitosis of the matrix continues unabated in almost all circumstances, and is only reduced at the point of death through starvation or shock.

The final day of the symposium began with another paper by Dr. Chase, who discussed the possible ways in which a resting follicle may be stimulated to begin a new phase of growth, and who confirmed the point made by Prof. Durward that a certain minimum number of hairs must be plucked before new growth will commence. He added the important information that in early telogen many more hairs must be plucked to stimulate growth than is necessary in late telogen, a result which suggests the possibility of a slow build-up of some natural stimulator during telogen. He then referred to the effects of radiation, and this subject was taken up in detail by Dr. Van Scott, who described a method of using hair roots as a tool for checking the effects of ionizing radiations on the body.

The nutritional problems of the growing hair were next discussed by Dr. M. L. Ryder (Wool Industries Research Association, Leeds) with special reference to wool. Carbohydrate and protein, but not fat, are evidently critically important, and Dr. Ryder went on to describe the results of experiments on the uptake of radioactive glucose and of radioactive cystine. The former is apparently absorbed predominantly by the hair bulb while the latter appears to enter higher up, just below the region of keratinization. Then followed a lecture by Dr. J. B. Hamilton (New York), who discussed what are evidently genetic differences in the rate of hair growth in Caucasian and Japanese men and women.

The final afternoon began with a review by Dr. M. P. Mohn (New York) of the effects on rat hair growth of the hormones of the gonads, adrenal, pituitary, thyroid, and islets of Langerhans. Inhibitory effects were described with the use of œstrogens, glucocorticoids, adrenalin, and adrenocorticotrophic hormone. Some stimulus was obtained with thyroxin and insulin. Other hormones were without effect. The symposium ended with a description by Dr. R. E. Billingham (University College, London) of the *de novo* formation of follicles in the adult. In disproving the theory that such new formation never occurs, he gave details of follicle production in the rabbit when a large wound is resurfaced with new epidermis, and in the deer during the annual production of new antlers. However, he pointed out that in normal adult mammals there is no evidence that this process ever occurs.

The symposium was clearly a great success and all those connected with its organization are to be highly congratulated. Under the general editorship of Prof. Montagna the various contributions are now to be collected and published in book form, and the result should be an invaluable review of the present state of knowledge of hair growth.

URANIUM, HELIUM AND THE AGES OF METEORITES

By Dr. GEORGE W. REED
Argonne National Laboratory
AND
Prof. ANTHONY TURKEVICH
Enrico Fermi Institute for Nuclear Studies, University of Chicago, Chicago, Illinois

THE recent measurements of the uranium contents of stone[1] and iron[2] meteorites permit a re-examination of the accumulated data on the rare gases present in meteorites with the object of establishing helium ages. These may refer to the time of accumulation of either radiogenic helium[3–7] or helium produced by cosmic rays[8–13]. In this report major emphasis will be on the radiogenic-helium ages of stone meteorites.

The uranium data on four chondrites indicate a constant uranium content of about $1{\cdot}1 \times 10^{-8}$ gm./gm. in such meteorites[1]. Within the accuracy (approximately 10 per cent) of the method used, the isotopic composition of the uranium in stone meteorites[1] appears to be the same as that of terrestrial material. The helium contents of meteorites have been reported by Paneth[3–7], Gerling[14–17], their co-workers, and others[12,13,18,19]. In many of the samples the isotopic composition of the helium has also been measured.

Four generalizations of existing data are necessary to determine ages from helium data. (1) It is assumed that the average uranium content of all chondrites for which no recent determinations have been made is $1{\cdot}1 \times 10^{-8}$ gm./gm. (2) The non-radiogenic helium is assumed to consist of about four helium-4 atoms for each helium-3 atom. The radiogenic helium in stone meteorites can then be estimated if the helium-3 content has been measured. Since the helium-3 contents of stones are usually small, the conclusions from this work are not seriously changed even by doubling the assumed helium-4/helium-3 ratio. (3) It is assumed that the ratios thorium/uranium and uranium-238/uranium-235 in meteorites are the same as those found terrestrially (3·6 and 137·8, respectively). A 30 per cent difference in the thorium–uranium ratio used will affect the calculated ages by about 10 per cent. (4) The rate of production of helium-3 (gm./yr.) from cosmic rays is taken to be $8{\cdot}2 \times 10^{-15}$ c.c. S.T.P. in stone meteorites. This is derived from a value of $5{\cdot}7 \times 10^{-15}$ c.c. S.T.P. helium-3/gm./yr. in iron estimated by Currie, Libby and Wolfgang[19] from their measurements on the formation of tritium by BeV. protons and corrected for the direct production of helium-3. The variation of the cross-section for the formation of tritium as a function of atomic number and the elemental abundances for meteorites used in the calculation are from Currie *et al.*[20] and Suess and Urey[21]. Other values[22,23] that have been used are within a factor of three of that given here. (The tritium–helium-3 data of Begemann, Geiss and Hess[18] give a value in agreement with that used here.)

The stone meteorites for which helium data are available and for which the uranium data are applicable are listed with descriptive information[24] in columns 1, 2 and 3 of Table 1. Columns 4 and 5 give the total helium and the helium-3 contents in 10^{-6} c.c. S.T.P./gm. of meteorite. Column 6 gives data on the uranium content in units of 10^{-8} gm./gm. The

(a) Helium contents in 10^{-6} c.c. S.T.P./gm.

(b) Uranium content and 3·2 × 10^9 age reported by Reasbeck and Mayne (ref. 7). The difference in radiogenic helium ages is probably due to the use of different approximations.

(c) Tilton, G. R., Ph.D. thesis, University of Chicago (1952).

(d) H^3–He^3 measurements give a cosmic-ray age of 0·24–0·28 × 10^9 yr. for this meteorite (ref. 13).

(e) Uranium content based on average for chondrites by Hamaguchi, Reed and Turkevich (ref. 1).

(f) See ref. 17.

(g) See ref. 15.

(h) The Russian results are summarized in ref. 17.

(i) Nuevo Laredo is reported to be a chondritic howardite by Patterson (ref. 28b).

calculated radiogenic ages are given in column 7; they lie in the range 0·5–4·5 × 10^9 years. Radiogenic ages measured by other workers (column 9) who used primarily the potassium-40–argon-40 method are listed in column 8. In eight cases out of eleven, the radiogenic helium ages agree with these to within 15 per cent. These eight cases of agreement can be added to the weight of evidence from meteorite age determinations[15] against a change of fundamental constants with time. The cosmic-ray ages deduced from the helium-3 content are listed in column 10. They are all significantly lower than the corresponding radiogenic ages and range from a few to about 300 million years.

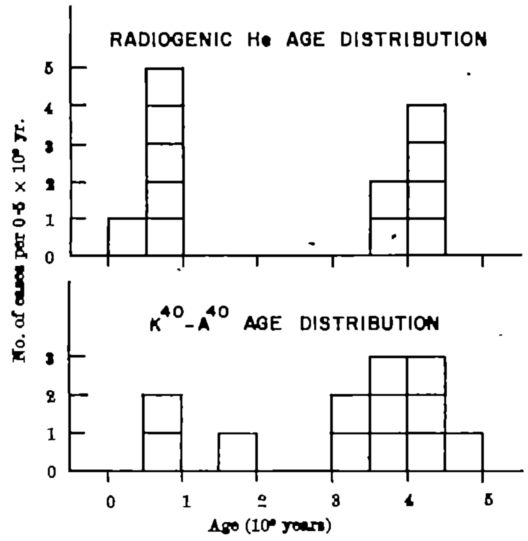

Fig. 1. Distribution of meteorite ages from radiogenic helium and potassium–argon measurements

The radiogenic helium ages for the stone meteorites fall into two distinct groups, one with values up to about 1 × 10^9 yr., the other with values of about 4 × 10^9 yr. This segregation is less clear-cut than previous age determinations, although a marked grouping of chondrites at 4–4·5 × 10^9 yr. has been emphasized by Geiss and Hess[17]. Fig. 1 shows the distribution in ages of these meteorites as determined by the radiogenic helium (top) and by the potassium–argon methods (bottom).

Two of the stone meteorites (Nuevo Laredo and Holbrook), however, show short ages by the radiogenic helium method, whereas the potassium–argon ages are long. The discrepancy is emphasized by the fact that in these two stones the uranium was actually measured, and in the case of Nuevo Laredo an even longer age (4·5 × 10^9 yr.) is deduced by a third method (lead–lead)[28a].

Among the possible explanations for the age grouping presented here is that the 4·5 × 10^9 year age measures the accumulation and segregation of all the meteoritic matter, and that some of the material lost its radiogenic helium about 10^9 years ago. This loss of helium was sometimes accompanied by a loss of radiogenic argon. (Reynolds and Lipson (ref. 19) suggest that the lower age for Nuevo Laredo, derived from potassium–argon measurement as against the lead isotope method, is due to severe heating late in the history of the object.) Such an occasion might have been the break-up of a parent body.

The cosmic-ray ages that we deduce from the helium-3 contents of stone meteorites vary from 5 to 300 million years. The recent and more accurate tritium–helium-3 measurement on the Norton County achondrite by Begemann, Geiss and Hess[13] gave a result of 240–280 million years and hence falls near the maximum of our range. Cosmic-ray ages are subject to the usual uncertainties arising from lack of knowledge of the size and shape of the meteorites before entering the Earth's atmosphere. The fact that the cosmic-ray ages are significantly lower than the corresponding radiogenic ages may be due entirely to the effect of self-shielding in the original meteorite. The possibility that these objects spent most of their time in regions of cosmic-ray intensity lower than that near the Earth must also be considered. However, the evidence would not seem to support the argument that radiogenic helium has been lost preferentially[30] to helium induced by cosmic rays in stone meteorites.

We wish to thank Mr. W. Nichiporuk for supplying translations of most of the Russian work to which we refer, and Dr. R. Marshall and Dr. F. Begemann for many helpful discussions.

HIGH-VOLTAGE PAPER ELECTROPHORESIS OF INORGANIC CATIONS: ALKALI, ALKALINE-EARTH AND OTHER METALS

By Dr. D. GROSS

Research Laboratory, Tate and Lyle, Ltd., Keston, Kent

THE importance of the alkali and alkaline-earth metals in biochemistry, nuclear science and industry has prompted suggestions for convenient micro-methods for the detection and estimation of these ions in mixtures or by themselves. Most of the methods recently proposed are based on polarography, flame photometry, chromatography and paper electrophoresis. Flame photometry has been successfully applied to sodium, potassium and calcium, although mutual interference and the presence of other cations and anions can become serious disturbing factors. Both chromatographic and electrophoretic procedures aim at a complete separation of the individual metals as salts, cations or anionic complex compounds. By none of the chromatographic techniques[1] can a satisfactory separation of all the alkali metals be achieved; and paper electrophoretic methods[2], although much quicker and unrestricted with respect to the presence of most anions, are unable to separate potassium, rubidium and caesium from one another.

By application of a high-voltage technique[3] with its attendant superior resolving power, the rapid, simultaneous separation of all the alkali metals (except ammonium) has been found feasible. As

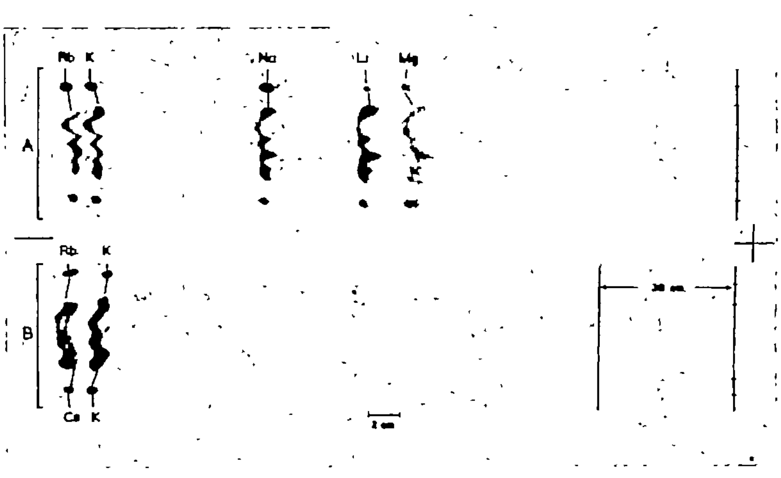

Fig. 1. Electrophoresis of the alkali metal ions

Conditions: (*A*) 100 V./cm., 12 m.amp./cm., Whatman No. 3 *MM*, 4 in. × 22½ in. strip, approx. 0·1 *M* ammonium carbonate solution, 7·9 gm./l., pH 8·9, mean temperature of cooling water 9° C., 23 min., sample applied 2 in. from anode end; spraying reagent, 0·01 per cent solution of bromothymol-blue (B.D.H.) in ethanol and water (9:1). (*B*) Same conditions as in (*A*), but run first for 20 min. to a distance of 38 cm., transferred to a new strip and run for another 17 min. to a total distance of 70·1 cm. Distances measured from starting line to leading edge of the rubidium band

Table 1

Cation	Ionic mobility at 18° C. in cm.^{2} V.$^{-1}$ sec.$^{-1}$	Relative rate of migration (Rb = 1 000)
K^+	64 6	0 962
Rb^+	67 5	1 000
Cs^+	68·0	0·988

shown by Fig. 1 (*A*) the separation of rubidium or cæsium from potassium and the other cations can be achieved in 23 min. at a potential gradient of 100 V./cm., and (*B*) the more difficult separation of rubidium from cæsium and the others requires 37 min. and a migration path of 70·1 cm. Since the effective length of the paper strip under existing experimental conditions is only 50 cm., a transfer method had to be adopted whereby the experiment was interrupted after 20 min., corresponding to a distance of 38 cm. travelled by rubidium, the anode end of the strip rolled back, the cathode end joined to a new strip and the run continued for another 17 min. Although the technique helped to overcome quite satisfactorily the limitations imposed by the dimensions of the available apparatus, for routine separations of mixtures of rubidium, cæsium and potassium an apparatus of a length of 80–100 cm. would be advisable. The relative rates of migration observed do not agree completely with the sequence of the ionic mobilities[4] calculated for free migration at infinite dilution, as Table 1 shows.

The discrepancy, however, is surprisingly small considering the fact that the conditions obtaining in paper electrophoresis, with possible adsorption and other migration-impeding effects, differ significantly from those in free migration at infinite dilution. It is interesting to note that the comparatively small difference of 1·2 per cent in migration-rates between rubidium and cæsium appears to be sufficient for a separation under the conditions described.

The best results were obtained by applying the samples to paper strips moistened with the buffer solution and blotted between two thick layers of filter paper. The choice of a conveniently volatile buffer such as an ammonium carbonate solution makes it possible to free the paper strip from buffer salts after the run by drying it for 10 min. at 80° C. and to locate the cations, presumably as their oxides, by means of a *p*H-indicator solution. Bromothymol blue proved most suitable in this respect by showing the cations with sharp contrast as blue spots on a practically white background, affording thus a sensitivity of 0·2 μgm. of sodium and potassium, and of 0·5 μgm. of lithium and magnesium. Spraying the strip lightly with distilled water before the indicator spray enhanced its sensitivity for magnesium. A procedure based on visual comparison of the sample with suitable standards has proved a rapid and convenient method with results in good agreement with control tests by flame photometry. A separation of potassium, sodium, lithium and magnesium can be obtained in 5 min. at 140 V./cm. The reproducibility of experiments has been greatly helped by the constant and uniform pressure control maintained by means of a basically simple pneumatic device consisting of an inflatable rubber or plastic bag and pressure gauge. Measurements by thermocouples of the temperature in the paper strip during electrophoresis to test the degree of efficiency of cooling have shown that the temperature can be up to several degrees higher than the mean temperature of the cooling water, if the pressure is not kept constant.

For the complete separation of the alkaline-earth metals, a citric acid buffer with its capacity for forming complexes was found most suitable and gave the electrophoretic migration sequences as illustrated in Fig. 2 (*B*). The position of magnesium is different from that reported by Evans and Strain[5] in a similar buffer solution, though not of exactly the same *p*H value; and according to them, magnesium is more anionic than calcium. The alkaline-earth ions were detected by spraying with alizarin *S* and subsequent exposure to ammonia vapour, a general reaction the sensitivity of which is highest for calcium and lowest for magnesium. The position of magnesium was confirmed by spraying magnesium and calcium with 8-hydroxyquinoline, followed by exposure to ammonia vapour[6] and viewing under ultra-violet light, in which magnesium shows a characteristic bright fluorescence.

Fig. 2, *A*, *B* and *C* (photographed under ultra-violet light) show the relative positions of the negatively charged complexes of fourteen cations run

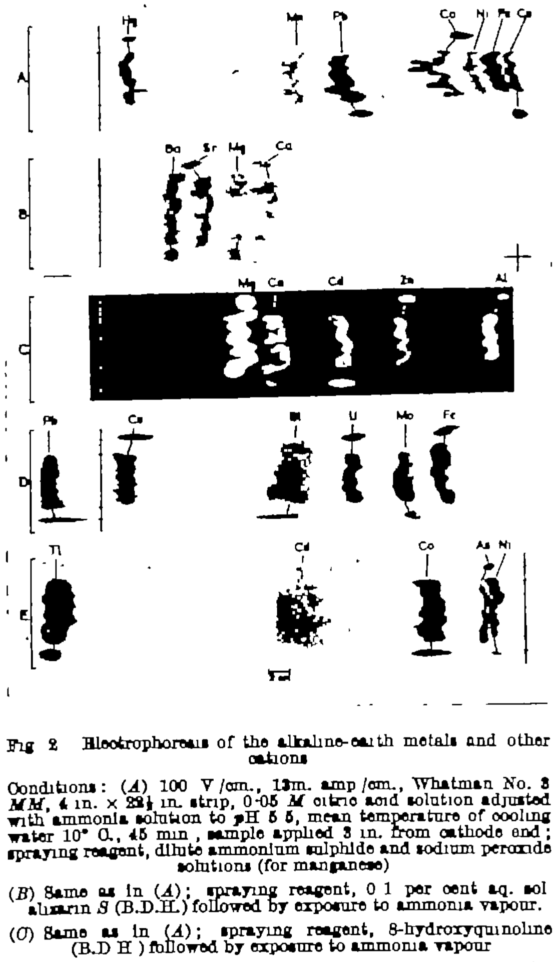

Fig 2 Electrophoresis of the alkaline-earth metals and other cations

Conditions: (*A*) 100 V./cm., 13m. amp./cm., Whatman No. 3 *MM*, 4 in. × 22½ in. strip, 0·05 *M* citric acid solution adjusted with ammonia solution to *p*H 5 5, mean temperature of cooling water 10° C., 45 min., sample applied 3 in. from cathode end; spraying reagent, dilute ammonium sulphide and sodium peroxide solutions (for manganese)

(*B*) Same as in (*A*); spraying reagent, 0 1 per cent aq. sol alizarin *S* (B.D.H.) followed by exposure to ammonia vapour.

(*C*) Same as in (*A*); spraying reagent, 8-hydroxyquinoline (B.D H.) followed by exposure to ammonia vapour

(*D*) 140 V./cm., 6·5 m amp./cm. Whatman No 3 *MM*, 4 × 22½ in. strip, 0 05 *M* citric acid solution adjusted to *p*H 3·1, mean temperature of cooling water 11° C., 30 min., sample applied 4½ in. from cathode end; spraying reagent: dilute ammonium sulphide solution for lead, copper and bismuth, potassium ferrocyanide for uranium, molybdenum and iron

(*E*) Same as in (*D*), but sample applied 2 in. from anode end and sprayed with dilute ammonium sulphide solution at *p*H 5·5 and a potential gradient of 100 V./cm. for 45 min. At *p*H 5·5, Fe^{2+} and Fe^{3+}, Ti^{4+}, UO_2^{2+} and Al^{3+} show a tendency to form at least two complexes of varying degrees of ionization producing on electrophoresis two bands. Only one band of Fe^{3+} is apparent in (*A*), as the faster band had left the strip. This effect, however, can be reduced to an insignificant minimum by decreasing the *p*H value of the buffer solution to 3·1, or 2·5 for Ti^{4+}. At *p*H 2·5 the non-complexed cationic Fe^{3+} can be rapidly separated from Fe^{2+}. Fig. 2 (*D*) and (*E*) show the relative positions of some cations after 30 min. at *p*H 3·1 and 140 V./cm., where uranium, applied either as uranyl nitrate or acetate, gives a particularly sharp band. The position of Mo^{6+} is interesting, since at *p*H 5·5 it is ahead of iron. Bi^{3+}, which migrates at the same rate as cobalt at *p*H 5·5, is well separated from it at *p*H 3·1, at which both bismuth and cadmium give fairly diffuse zones. (*E*) shows that some of the ions migrate as non-complexed cations, among which Tl^{+} shows an outstanding mobility. In addition, a mixture of Sb^{3+}, Sn^{2+}, Cd^{2+} and As^{3+} can be separated at *p*H 5·5, and a mixture of Mo^{6+}, V^{5+} and Ti^{4+} at *p*H 2·9.

The time required, though already short, can be appreciably reduced if similar but simpler mixtures are treated.

Thanks are due to Mr. H. C. S. de Whalley, director of research, for encouragement, Mr. R. W. Butters for valuable technical assistance, Mr. D. G. Harrison for skilful photographic reproductions and to the Directors of Tate and Lyle, Ltd., for permission to publish this communication.

ALTERATIONS IN FELINE BEHAVIOUR FOLLOWING BILATERAL AMYGDALECTOMY

By P. J. MORGANE and Prof. A. J. KOSMAN

Medical School, Northwestern University, Chicago

THIS experiment was designed to study the behavioural effects of bilateral removal of the amygdaloid complex in the cat and to study any further alterations produced by subsequent neodecortication. This article will deal only with the first part of the study, that is, the effects of bilateral amygdalectomy.

Previous studies by several workers have produced a wealth of conflicting information regarding the behavioural effects of this procedure in both acute and chronic experiments. Both rage behaviour[1,2] and placidity[3,4] have been described, presumably from similar operative procedures, as well as alterations in sexual behaviour[3,4] and eating activities[4-6].

In the present study, nine mature cats, six females and three males, were observed and studied for several weeks after their adjustment to laboratory conditions. These observations included general cage activity, reactivity to routine care, response to petting, degree of aggressive behaviour induced by application of noxious stimuli, and reactions to other animals.

Bilateral amygdalectomy was performed in two stages at approximately one-month intervals. The amygdaloid nuclei and pyriform lobes were removed by suction methods after proper exposure of the temporal lobes by means of a trans-temporal trepanation. Recovery in the first post-operative week was supported with antibiotics and fluid therapy, and in most cases by the second week post-operatively spontaneous eating was resumed and recovery thereafter uneventful. Tests similar to those carried out pre-operatively were instituted with particular emphasis being placed on alterations in the pre-operative rage thresholds and responses to pleasurable stimuli, as well as any alterations in sexual behaviour and eating activities.

With the exception of a moderate hyperactivity and hypervocality, both of which persisted for some six weeks after the second operation, general behavioural changes were conspicuously absent. Rage thresholds were not significantly altered from their pre-operative levels as determined by the application of threatening and painful stimuli. No alterations in sexual behaviour were seen, although animals of different sex were frequently placed together. There was no increment in so-called 'pleasure' reactions as previously described by Schremer and Kling[3] or any noticeable 'taming' as a result of the operative procedure. It was, however, observed that domestic stock cats often become more tractable under laboratory care, and it is pertinent to point out that the assessment of 'docility' or 'placidity' is very difficult in this species. In our experience, several animals of extremely nasty temper became in time well adjusted to their new environment without any operative procedure being performed.

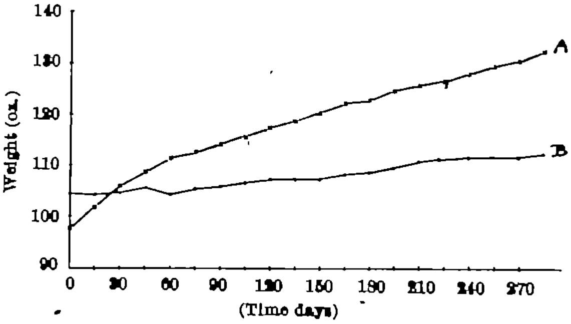

Fig. 1. Weight changes: *A* in amygdalectomized cats (9 animals) from low weights after second operation; *B*, in control cats (7 animals) from initial laboratory weights, over a period of 285 days

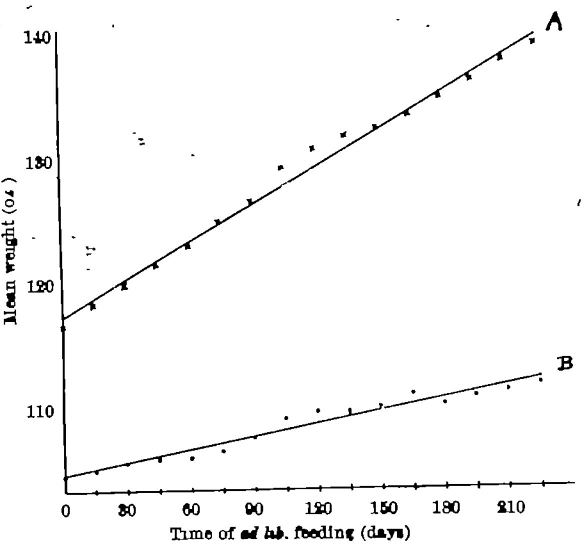

Fig. 2. Regression lines of amygdalectomized and control cats over a 225 day period of *ad libitum* feeding. *A*, amygdalectomies (9 animals); regression line, $Y = 116 \cdot 84 + 1 \cdot 39 X$; *t* value for slope = 36·68 ($P < 0 \cdot 001$). *B*, controls (7 animals); regression line, $Y = 105 \cdot 77 + 0 \cdot 469 X$; *t* value for slope = 11·96 ($P < 0 \cdot 001$). Differences between slopes, $P < 0 \cdot 01$

Weights were determined on all animals pre-operatively and also at regular intervals in the post-operative period. The one behavioural change that expressed itself in the post-operative period was a definite hyperphagia in all of the amygdalectomized animals. These were compared with four normal cats and three bilaterally decorticate cats serving as controls.

Initially, there was no significant difference in the mean weights of the experimental animals (100·6 oz.) as compared to the control group (104·6 oz.), and there was no significant difference between the two groups serving as controls, these latter, therefore, being grouped as one. Fig. 1 shows weight as a function of time, the weights of the experimental animals being plotted from the low-point after the second operation and all the controls from their initial laboratory weights. Direct group comparison testing showed that the weights of the experimental group were not significantly different from the controls until approximately the 90-day point on the time-scale.

Table 1. FOOD INTAKE OF AMYGDALECTOMIZED AND CONTROL CATS OVER TWO THREE-DAY PERIODS

Group	*n*	Mean weight (gm.) of horse-meat eaten/day over two 3-day test periods (dry wt.)
Amygdalectomies	9	154·38 ± 6·57
Controls	7	125·87 ± 3·93

± s.e. Difference between amygdalectomies and controls: $P < 0 \cdot 001$.

In order to evaluate properly this weight change in the experimental group *ad libitum* feedings were started on all animals, experimental and controls. Following this procedure, the experimental group continued to gain weight at a more significant rate as compared to the controls.

Fig. 2 shows the regression lines of the amygdalectomized animals and the control group. Regression of weight on time from the date of initiation of *ad lib.* feedings reveals the rate of weight gain of the amygdalectomized animals to be significantly greater than that of the controls, the differences between the slopes being significant at a probability of less than 1 per cent. The trend of the experimental group can best be described by the linear regression $Y = 116 \cdot 84 + 1 \cdot 39 X$. This slope is significantly different from zero at a probability of less than 0·1 per cent. The trend of the control group can best be described by the linear regression $Y = 105 \cdot 77 + 0 \cdot 469 X$, this slope also being significantly different from zero at a probability of less than 0·1 per cent.

In order actually to determine whether or not there really was an increase in food intake, the daily food rations were weighed over two three-day periods. Table 1 shows that the amygdalectomized animals consumed a mean of 154·38 gm. of food daily (dry weight), whereas the control group consumed 125·87 gm. daily (dry weight), the differences in food intake by group comparison being significant at the 0·1 per cent level of probability. Table 2 shows the changes in weight of the amygdalectomized and control animals over the entire period of observation with probability-levels between the different periods.

This study reveals that a significant gain in weight and increase in intake of food result from bilateral amygdalectomy in the cat. Several previous studies have rather casually referred to alterations in eating behaviour after medial temporal operations, notably those of Kluver and Bucy[4] and Pribram and Bagshaw[5] in the monkey, and Fuller, Rosvold and Pribram[6] in dogs. The only quantitative study is that of Anand and Brobeck[7] in rats and cats. After stereotaxic destruction of the amygdaloid nuclei they did not obtain any alteration in food intake in those animals in which the lesions were restricted to the amygdala. It may be pointed out that not only was the method different from our own, but also that all the animals in this group were killed at an early date, within six to eight weeks of the surgical procedure.

Although all our experimental animals have shown a significant gain in weight as compared with the control group, this gain in body-weight has in no

Table 2. WEIGHT CHANGES OF AMYGDALECTOMIZED AND CONTROL CATS OVER THE ENTIRE PERIOD OF OBSERVATION WITH PROBABILITY LEVELS BETWEEN THE DIFFERENT PERIODS

Group	*n*	I Mean initial weight (oz.)	II Mean weights at time of *ad lib.* feedings (oz.)	III Mean weights 225 days *ad lib.* feeding (oz.)	Mean % gain I–III
Amygdalectomies	9	100·60 ± 4·66	117·60 ± 4·03	138·40 ± 4·28	38·90 ± 4·95
Controls	7	104·60 ± 3·89	106·20 ± 3·95	112·90 ± 3·82	8·08 ± 1·10

± s.e.

PROBABILITY

Amygdalectomies *vs.* Controls (direct comparison)	I : $P > 0 \cdot 40$	II : $P > 0 \cdot 05$	III $P < 0 \cdot 001$
Amygdalectomies *vs.* Controls (differences in weight)	I *vs.* II : $P < 0 \cdot 001$		II *vs.* III : $P < 0 \cdot 001$

case been as marked as that reported by other observers following lesions in the ventro-medial hypothalamic nuclei[8,9]. In our animals the mean percentage gain over the entire period of observation was, as seen from Table 2, 38·90 per cent for the experimental animals and 8·08 per cent for the controls, whereas doubling of the body-weight over similar periods has by no means been uncommon with hypothalamic lesions. From this, it can be said that the amygdaloid complex may constitute one means of control of feeding activity in the cat. In this respect it is significant to recall the existence of strong anatomical connexions between the amygdala and the ventro-medial hypothalamic nucleus.

Due to the fact that our studies are still in progress, anatomical control cannot be given and the extent of the lesions is not yet known. However, it is difficult to postulate what other structures in this general region could account for the observed hyperphagia. Extension of the lesion medially would invade the lateral hypothalamus, lesions of which have been shown to produce aphagia[10], opposite to what we have obtained.

STRUCTURE OF THE LIQUID-CRYSTAL PHASES OF THE SOAP – WATER SYSTEM: MIDDLE SOAP AND NEAT SOAP

By Dr. V. LUZZATI, H. MUSTACCHI and A. SKOULIOS
Centre de Recherches sur les Macromolécules, Strasbourg

THIS communication describes an X-ray diffraction study of the middle soap and neat soap phases of the soap – water system.

The phase diagram shown in Fig. 1 is that of the system potassium palmitate – water[1], but is characteristic of soap – water systems in general. Below the curve T_c, in Fig. 1, is the region of gel and coagel in which the system is not always in equilibrium. Above the curve T_i there is isotropic solution. In the region between these two curves the system shows properties characteristic of liquid crystalline structures (high viscosity, optical anisotropy, etc.). The middle soap and neat soap, with which we are here concerned, form two distinct phases in this region.

X-ray diagrams were obtained with a Guinier-type focusing camera and a bent-quartz monochromator. The camera was evacuated, and the specimen could be maintained at temperatures from 20° to 150° C. A Philips diffractometer, to which a bent-quartz monochromator was fitted, was also used.

Measurements on the sodium and potassium salts of a number of saturated fatty acids in the range C_{12}–C_{18} all gave similar results. We describe here the results of a systematic study of the structure of potassium palmitate (KC_{16}) as a function of concentration (10–90 per cent soap) and temperature (20°–100° C.).

Variation of X-ray diagrams with concentration. The X-ray diagrams show a considerable variation with concentration. For example, at 100° C. (see Fig. 1) the following results are obtained.

In the micellar region (concentration 10–30 per cent) the diagrams show only diffuse bands. At all higher concentrations—that is, in the anisotropic zone—lines as fine as those given by crystalline materials are observed. At about 30–33 per cent concentration, in the zone between the micellar and the middle soap phases, the diagrams contain both the diffuse bands of the micellar and the sharp lines of the middle soap structures.

At about 33–53 per cent concentration, in the middle soap region, there is a series of sharp lines corresponding to Bragg spacings in the ratio $1 : 1/\sqrt{3} : 1/\sqrt{4} : 1/\sqrt{7}$. The only other feature of the diagrams, in this concentration range, is a weak and diffuse band at about 4·5 A.

At about 64–87 per cent concentration, in the neat soap region, the X-ray diagrams contain from two to five lines giving Bragg spacings in the ratio $1 : 1/2 : 1/3 : 1/4 : 1/5$. Again, the only other feature is the weak, diffuse band at about 4·5 A.

In the intermediate zone, at concentrations of about 53–64 per cent, the X-ray diagrams are complex, and are not simply a superposition of the middle soap and neat soap diagrams.

Variation of X-ray diagrams with temperature. Change of temperature at constant concentration

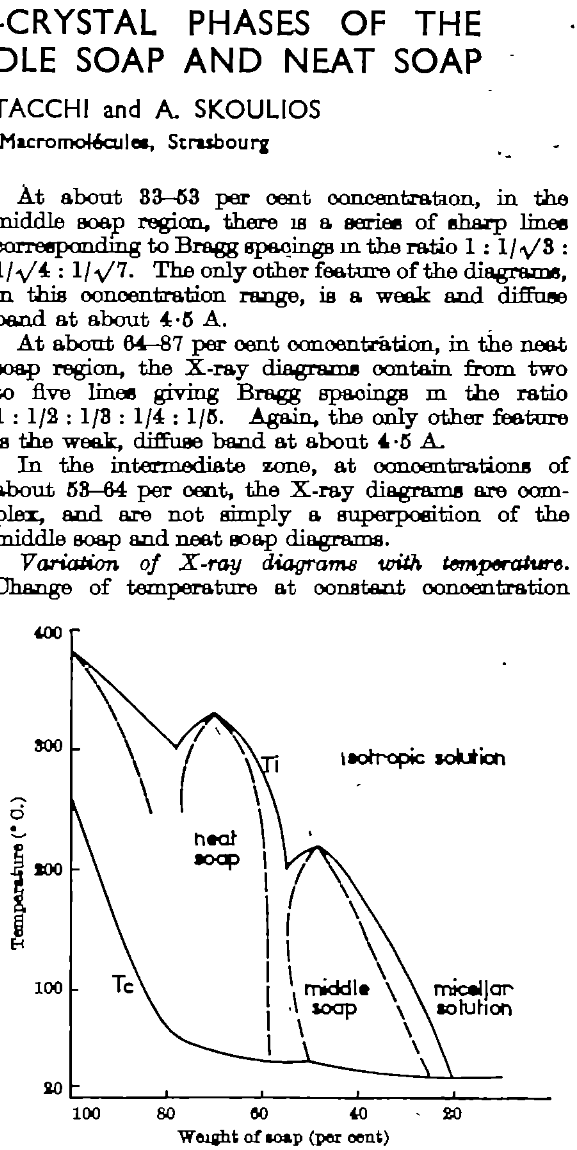

Fig. 1. Phase diagram of the potassium palmitate – water system

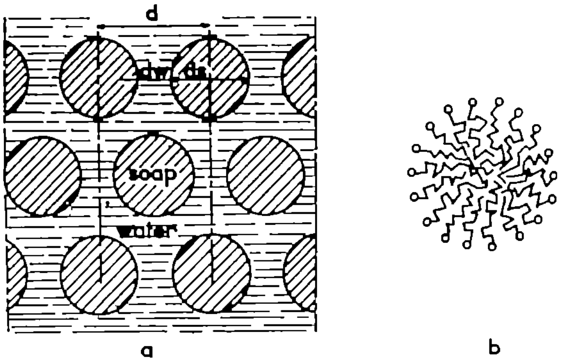

Fig. 2. (*a*) Schematic structure of middle soap; (*b*) cross-section of a cylinder

produces no change in the general character of the X-ray diagram, provided that no phase boundary is crossed; that is, within these limits, the ratio of the Bragg spacings characteristic of the phase concerned is preserved. However, the spacings themselves decrease as the temperature is increased: the linear thermal coefficient is -1×10^{-3} to -2×10^{-3} per deg. C. This effect is characteristic of a structure which is partially 'liquid', and is observed in certain partially extended polymers. (Note that, under the same conditions, the thermal expansion of the large parameter of crystalline soap is $+5 \times 10^{-5}$ per deg. C.)

It has been shown[2] that the coefficient of thermal expansion of a random coil, partially extended by the application of equal and opposite forces at its extremities, is given by:

$$\alpha = \frac{dr}{r dT} = -\frac{1}{T}$$

where r is the distance between the two ends of the chain. For $T = 373°$ K. this gives $\alpha = -2 \cdot 68 \times 10^{-3}$. Assuming that the thermal expansion of water is negligible, it is possible to calculate the diameter of the cylinder (in the middle soap) and the thickness of the double soap layer (in the neat soap) (see below) at different temperatures, and to compute the thermal expansion coefficient of the soap alone: the average value obtained is $\alpha \simeq -3 \times 10^{-3}$. The agreement between the theoretical and the experimental value of α is excellent.

These results suggest that, in both middle soap and neat soap, the hydrocarbon chains are disordered but have some degree of preferential orientation in the direction perpendicular to the soap – water interface. Further evidence that the chains are more nearly 'liquid' than 'crystalline' is provided by the fact that the diffuse band at 4·5 Å. is identical with that given by liquid hexadecane.

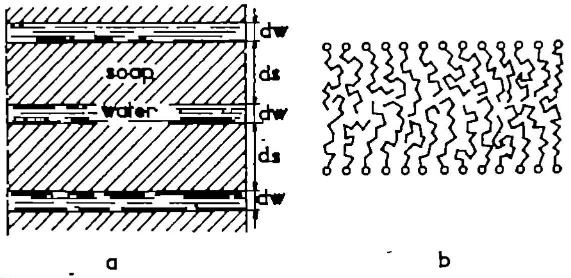

Fig. 3 (*a*) Schematic structure of neat soap; (*b*) section of a soap double layer

Middle soap: The X-ray diagrams indicate the presence of a structure consisting of long, identical, parallel rods in regular hexagonal array. The polar groups of the soap molecules must, presumably, lie at the surface of these rods, and the hydrocarbon chains in the interior. From the distance between the axes of the rods (given by the X-ray diagrams), the concentration of the soap and the density of the soap (taken to be 0·9 gm./cm.^{3}), the diameter of the rods (assuming that the rods are circular cylinders) and the thickness of the layer of water between them can be calculated. The results are shown in Table 1 (see Fig. 2*a*).

Table 1

Soap concentration (per cent)	*d* (in A.)	*ds*	*dw*
31·4	62·0	37·8	24·2
35·4	59·0	38·1	20·9
40·4	55·8	38·4	17·4
44·3	53·5	38·5	15·0
46·1	52·8	38·7	14·1
48·2	51·0	38·2	12·8
51·4	49·8	38·4	11·4

It is clear that the diameter of the rods is independent of the concentration of soap in the middle soap phase. The 'liquid' hydrocarbon chains fill the interior of the rods uniformly (see Fig. 2*b*).

Neat soap: The X-ray diagrams indicate a structure consisting of parallel, equidistant sheets. These sheets are, presumably, formed of a double layer of soap molecules, and separated from one another by a layer of water. From the inter-sheet spacing and the density and concentration of the soap, the thickness of the sheets and of the layer of water between them can be calculated. The results are given in Table 2 (see Fig. 3*a*).

Table 2

Soap concentration (per cent)	*d* (in A.)	*ds*	*dw*
67·7	37·4	26·2	11·2
70·0	36·4	26·3	10·1
73·3	35·8	27·0	8·8
76·4	35·8	28·0	7·8
80·0	35·9	29·3	6·6
81·9	36·3	30·3	6·0
84·9	36·4	31·4	5·0
87·9	37·1	33·0	4·1
Crystal 100	40·1	40·1	0

As the soap concentration increases, the thickness of the sheets increases and that of the water layer between them decreases. The increasing thickness of the double layer of soap molecules must be attributed to a stiffening of the hydrocarbon chains as the structure approaches that of an anhydrous soap crystal (see Fig. 3*b*).

The two structures described above are types of liquid crystals. In the Friedel classification, the neat soap is smectic. The middle soap structure resembles Friedel nematic 'stase', but has an additional degree of order, the structural elements being not only parallel but also equidistant. This may be compared with the structure of concentrated solutions of tobacco mosaic virus, described by Bernal and Fankuchen[3].

Radio Observations of the Comet Arend-Roland

THE observation of radio emission from the Comet Arend-Roland has been reported[1] at 600 Mc./s. and[2] at 27·6 Mc./s. The reported flux densities are of the order of 5×10^{-23} (private communication) and 5×10^{-22} W.m.$^{-2}$ (c./s.)$^{-1}$ respectively, or about 2 per cent and 3,000 per cent of the flux density of the quiet Sun. Observations[3] at 400 Mc./s. failed to detect any emission, though the sensitivity was high enough to detect a flux density less than 10^{-24} W.m.$^{-2}$ (c./s.)$^{-1}$.

Observations were made at Cambridge during periods between March 12 and May 13 in an attempt to detect radio emission from the comet at frequencies of 38 and 81·5 Mc./s., and by observing radio stars through its tail to derive information on the electron density, in the manner used by Hewish[4] in investigating the outermost layers of the solar corona.

Five different instruments were used. Two were interferometers of large resolving power used to detect any scattering of the radiation from radio stars situated behind the comet's tail. These instruments also enabled a very low limit to be placed on the radio emission from the head. The possibility of radio emission from the extended tail was investigated with interferometers of smaller resolving power, but these were of lower sensitivity, so the derived upper limit of intensity is greater.

In no case was any detectable effect observed; the upper limits of the flux density are given for the different periods in Table 1. A number of records were spoiled by intense emission from the Sun, and some at 38 Mc./s. by man-made interference; the best observations at this frequency were therefore obtained at night near lower culmination when the comet had moved sufficiently far north.

Solar emission also prevented the observation of three comparatively intense radio stars through the comet's tail. The observation of weaker stars was possible on a number of occasions between April 13 and May 13, but none of these was sufficiently well defined on the records to allow an individual measure of the scattering produced. It was, however, possible to show that there would be detectable changes in the record amplitude if all the weaker unresolved radio stars situated behind the tail were obscured or were subject to scattering greater than the resolution of the interferometer. No such effect was found, and it may therefore be concluded that the irregular variations of electron density in the tail of the comet were insufficient to produce scattering as great as ¼° at 81·5 Mc./s. or 1° at 38 Mc./s.

Table 1

Frequency (Mc./s.)	Interferometer spacing (wavelengths)	Maximum diameter observable (degrees)	Dates	Upper limit to flux density of comet ($\times 10^{-24}$ W.m.$^{-2}$ (c./s.)$^{-1}$)
81·5	120	1/4	April 13–24	3
			April 25–May 8	0·5
	10	3	April 13–May 8	5
	5	6	March 12–20	60
38	60	1/2	April 11–23 (4 days)	3
			(3 days)	15
			April 26–May 4	0·5
			May 5–13	0·25
	10	3	March 21–April 24 (10 days)	40

The magnitude of the scattering produced by an irregular region depends on ΔN, the root-mean-square departure of the electron density from the mean value, and l, the scale of the irregular structure[4]. The present observations indicate that $\Delta N/\sqrt{l}$ is less than 100, when ΔN is measured in electrons per cm.^{3} and l in kilometres.

Optical photographs of the tail of the Comet Arend-Roland show structure as fine as 10,000 km., leading to an upper limit of 10^4 for ΔN; it is probable that finer structure exists, and the limit of ΔN would then be smaller.

Rotational Analysis of the Tantalum Oxide Bands

BANDS of the tantalum oxide molecule have been photographed in the ultra-violet and the visible regions on a 21-ft. concave grating in the Department of Physics, University of Stockholm, in the first order, giving a reciprocal dispersion of about 1·2 A./mm. The previous analyses[1] are found to be incorrect. The revised analysis shows that the bands in these regions can be divided into two systems *A* and *C*. Bands of system *C* consist of two sub-systems with their (0,0) bands at νν24064 and 23348. Rotational structure of the (2,0), (3,1), (1,0), (2,1), (0,0) and (0,1) bands of system *A*, (1,0) and (0,0) bands of the sub-system ν24064 and (1,0), (0,0) and (0,1) bands of the other sub-system of *C* has been analysed. Bands of system *A* show only two branches each and are ascribed to the transition $c^2\Delta_{5/2}$–$a^2\Delta_{3/2}$. Strong *Q* branches are very prominent in all the bands of system *C*. Large Λ-type doubling is observed in the upper state levels and is found to vary linearly with *J* in the sub-system ν23348. The bands are ascribed to the transition $b^2\Pi$–$a^2\Delta$. All three states involved belong to Hund's coupling case (*a*). The vibrational and rotational constants obtained are given in Table 1.

Table 1. CONSTANTS OF TANTALUM OXIDE

State	ω_e (cm.$^{-1}$)	$x_e\omega_e$ (cm.$^{-1}$)	B_e (cm.$^{-1}$)	α_e (cm.$^{-1}$)	r_e (A.)
$c^2\Delta$	903·01	4·15	0·3775	0·0019	1·743
$b^2\Pi$	898·5 896·0	4·1	0·3772	0·0019	1·744
$a^2\Delta$	1,031·7	5	0·4020	0·0020	1·687

The coupling constant A for the $b^3\Pi$ state is of the order of 1,000 cm.$^{-1}$, while that of $a^3\Delta$ is either about 300 or 1,700 cm.$^{-1}$ according as the state is regular or inverted. It could not be ascertained whether the two states are regular or inverted; however, either both states are regular or both inverted.

The Compound Polarizer

The compound polarizer is a device for producing beams of polarized light of variable colours in the field of a microscope ocular. The polarizer proper consists of a disk of 'Polaroid', a disk of polythene and a disk of 'Rayophane', in that order from the light source; each of these disks can be rotated around a common axis. The analyser consists of a disk of 'Polaroid' within the microscope as near the objective as possible; it is fixed with respect to rotation but can slide upwards and downwards as objectives are changed by rotation of the microscope nosepiece. The beam of light passing through to the specimen examined must be convergent, a condition fulfilled by the ordinary substage condenser with no lens removed. The polarizer and analyser are in the fully uncrossed position relative to each other. The assemblage works as follows.

Plane polarized light coming from the polarizer is rotated by the polythene disk, and whatever elliptical polarization the light undergoes in traversing this disk is increased as the light traverses the 'Rayophane' disk. Accordingly, a beam of white light from the source is seen as coloured light through the microscope. The colour will vary according to the rotation of both the 'Rayophane' and polythene disks about the common axis. The standard setting is that which produces a well-marked lilac colour, the colour of the flower of *Syringa vulgaris*. A graded series of other colours is produced by rotation of the polythene disk clockwise or anti-clockwise. Rotated in one direction we get the series red, orange, yellow, white; rotated in the other direction we get the series deep blue, light blue, greenish-blue, white. In either case the colour is more and more diluted with white light as we move towards the white end-point, but the red, orange and blue colours are quite intense. The lilac 'background' colour corresponds to the darkening of the field obtained in the crossed-nicols position with plane polarized light, as can be shown by spectroscopic examination. When a colour filter is enclosed in the light source, a corresponding darkening is obtained by rotating the polythene disk in such a direction and to such an amount as would give a background colour complementary to the coloured light used. These analogues to the crossed-nicols position give the best results in the examination of anisotropic material. Isotropic material takes the background colour. In all cases it is advisable to use the ground-glass diffusion screen below the condenser, the common 'Daylight' filter being the most suitable.

This device enables the worker to carry out 'optical sectioning' of anisotropic material in the specimen because of the remarkable separation of the focal planes of differently coloured elements orientated at different angles. The function of the polythene disk is twofold: it produces the graded spectral series of colours (green excepted) already mentioned, and it 'gears down' the rapidity of transition from one colour to the next. 'Styrafoil', referred to by Gaythorpe[1] in an earlier communication, has much the same effect, but the colour change is much more rapid and the resolution of the image does not seem to be so good as with polythene. The polythene used is that employed for the manufacture of cosmic-ray balloons. 'Rayophane' is that manufactured by the British Rayophane Company, Ltd., and supplied to John Player and Sons, Ltd. It has an average thickness of 23μ, and for the best results sections examined by this method should have a minimum thickness approaching this. Sections of 50μ thickness are useful for many purposes where the general disposition of anisotropic elements rather than fine detail is required. Apart from its obvious use with skeletal and epithelial tissues, the method seems to have a special field of application in the examination of the central nervous system. Frozen sections of the central nervous system, mounted in glycerol or glycerol jelly, can be made to show the precise disposition and course of myelinated fibres to, through and from the grey matter, by rotating the stage. Full details of theory and practice will be submitted for publication later to the *Irish Journal of Medical Science*.

I thank Messrs. British Rayophane, Ltd., for supplying very full details of the nature and manufacture of 'Rayophane'. It should be mentioned that the material inadvertently called 'Cellophane' in the earlier communication from Fahy and MacConaill[2] was in fact 'Rayophane', kindly given by Messrs. Players (Dublin) to me.

Excess Zinc in Zinc Oxide

A method for determining excess zinc in zinc oxide has been devised[1]. It is based on measurement of the hydrogen produced by the excess metal when the sample is dissolved in hydrochloric acid. It will detect 0·05 μgm. of excess zinc. This communication summarizes the results obtained by the method with oxide in various states.

Dark orange and pale green single crystals, obtained through the courtesy of the National Smelting Co., Avonmouth, and believed to be of high purity, but non-stoichiometric, contained respectively 25·3 and 6·3 p.p.m. excess zinc/zinc oxide by weight (1 p.p.m. excess zinc/zinc oxide by weight = $1 \cdot 25 \times 10^{-6}$ fractional excess of cations). Heating the crystals at 1,300° C. in air (30 min. followed by cooling to room

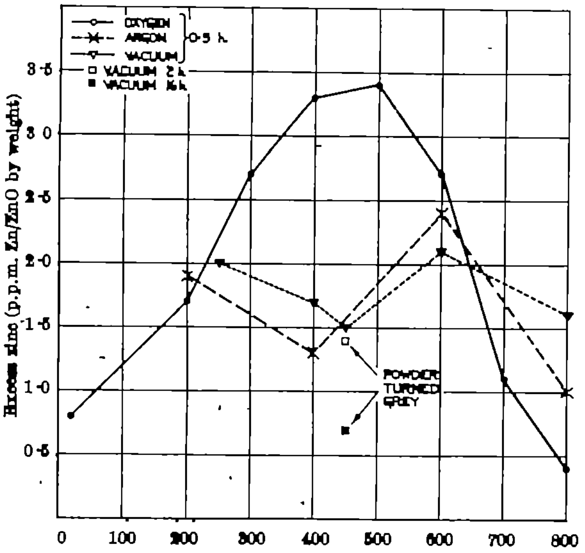

Fig. 1

temperature in less than 1 min.) reduced the excess zinc to 2·3 and 3·1 p.p.m. respectively. (The values quoted throughout this communication are usually the mean of at least two measurements.)

Pressings of zinc oxide powder (analytical reagent grade or better) which were sintered in air or oxygen at 1,000–1,200° C. contained excess zinc in the range 1·7–5·6 p.p.m. On the other hand, sintering in argon (containing not more than 10^{-3} mm. mercury pressure of oxygen) at 1,300° C. gave 13·0–18·0 p.p.m., while a loose powder also heated in argon at 1,300° C. gave 16·8 p.p.m.

The above results showed the expected change of non-stoichiometry with the oxygen content of the surrounding atmosphere. But at lower temperatures the opposite behaviour was observed.

Fig. 1 shows the effect on the excess zinc content of heating a powder (as made by the indirect process and stored in air; analytical reagent grade or better, 0·1–1 micron diameter particles) for 30 min. at temperatures up to 800° C. in oxygen, in argon or *in vacuo* (about 10^{-4} mm. mercury pressure outside the powder), with cooling to room temperature in gas or *in vacuo* as appropriate in 5 min. The well-defined maximum in oxygen, the minima *in vacuo* and in argon, all at 400–500° C., will be noted. They may perhaps be connected with the appreciable adsorption of oxygen[2] and the dissociation of the oxide *in vacuo* after previous exposure to oxygen[3], both reported in this temperature-range. (The identity of temperature of the present and previously reported phenomena probably constitutes the strongest evidence for non-stoichiometry rather than free zinc in the heated powders.)

Heating *in vacuo* at 450° C. for longer periods reduced the excess zinc content (Fig. 1) and the powder turned grey[3,4]. Similar behaviour of a second powder was observed. Thus grey oxide is not rich in excess zinc, either in the lattice or as free metal. Only zincite could be detected on examination of the grey powder by electron diffraction. A reduction of non-stoichiometry at the onset of dissociation may be implied. This phenomenon was reported[5] for cadmium oxide at higher temperatures.

A reduction of excess zinc with time *in vacuo* at 450° C. was also observed with crushed sintered material (about 50-μ single-crystal particles) initially containing 17·8 p.p.m. excess zinc. The values after 0·5, 2·0 and 16 hr. were respectively 10·3, 7·7 and 0·5 p.p.m. (If diffusion of excess zinc out of the particles were controlling the rate, the diffusion coefficient for excess zinc at 450° C. would have been of the order 10^{-16} cm.^{2} sec.$^{-1}$.)

The powder giving the results in Fig. 1 initially contained 0·8 p.p.m. excess zinc. However, analysis of eight other powders made by the indirect process showed that the initial excess zinc content was not always so small, contents up to 5·9 p.p.m. being found. There appeared to be a correlation between the excess zinc and sintering behaviour. The sintering of powder containing more than about 2·5 p.p.m. was enhanced[1] by oxygen, while that of powder containing less excess zinc was retarded by oxygen. This result also favours non-stoichiometry rather than free zinc.

The highest content of excess zinc observed, 42·9 p.p.m., was found with bright yellow powder (particles of 1 micron diameter or less) produced by scraping sintered material (3·3 p.p.m.) with a non-metallic knife.

Ehret and Greenstone[6] and von Wartenburg[7] found excess zinc in zinc oxide within the range 0·02–1 per cent, but the method of preparation of the specimens in each case gives grounds for believing that these relatively high figures may not entirely represent non-stoichiometry.

Mr. D. Clark is thanked for the electron diffraction work and Messrs. C. Wheeler and G. Christie for other experimental help.

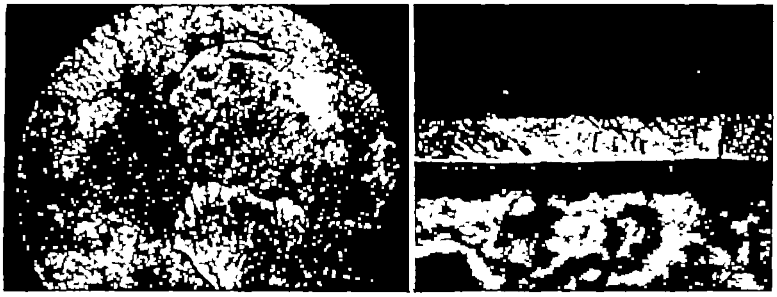
Grain-Growth in Metals by Cyclic Stress

It is well known that the crystal grains constituting a metal are fragmented into crystallites by the application of a cyclic stress greater than the endurance limit. Little is known, however, as to the grain-growth in a plating metal caused by cyclic stress.

When a specimen of steel which is plated with copper is submitted to reversals of cyclic stress, the micro-grains in the plating metal grow to a considerable size when the magnitude of the cyclic stress passes a certain limit. This limiting value of the cyclic stress is very near the endurance limit of annealed copper.

An examination by microscope of the surface and cross-section of a specimen after loading, electro-polishing and etching, reveals the growth of grains



Figs. 1 and 2. Grown grain and original micro-grains, after direct stress of ± 20 kgm./mm.^{2} for 5 × 10^6 cycles. × 1,000

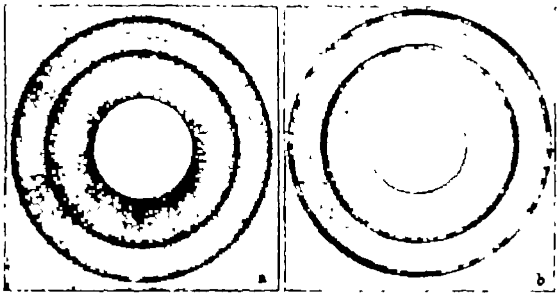


Fig 3. X-ray pattern: (a) before loading; (b) after direct stress of ± 22 kgm./mm.^{2} for 11 × 10^6 cycles

in the plating metal. Figs. 1 and 2 are micrographs of the plating metal showing grains which have grown and the neighbouring original micro-grains. Comparison of the X-ray patterns, before and after loading, also suggests the growth of grain due to cyclic stress. The X-ray patterns before and after loading are shown in Fig. 3. The stress indicated underneath each figure is not the true value in the plating metal but is a nominal one based on the elastic moduli of the steel base.

Separation of Talosamine from other 2-Amino Hexoses

In a sample of N-acetylgalactosamine prepared by the N-acetylation of galactosamine isolated from sheep tracheal cartilage, a substance has been detected which gives the reactions of an N-acetyl-2-amino hexose but which is not N-acetylgalactosamine or N-acetylglucosamine.

The preparation of N-acetylgalactosamine was examined by paper chromatography in several solvent systems. When sprayed with the hexosamine reagents to reveal N-acetyl-2-amino aldoses[1], two reddish-purple spots appeared; one of these occupied a position identical with that of N-acetylgalactosamine, whereas the other differed in position from both N-acetylgalactosamine and N-acetylglucosamine. When chromatograms were sprayed with anisidine hydrochloride, the light-brown colour produced in the position of the new spot indicated that it was probably due to an N-acetylhexosamine, since only N-acetylhexosamines have been observed to give this colour under these conditions (Davies, D. A. L., and Crumpton, M. J., unpublished work). The *R*(glucose) values on Whatman No. 1 paper for the new sugar, N-acetylglucosamine and N-acetylgalactosamine in butanol/pyridine/water (3 : 2 : 1·5), were 1·46, 1·28 and 1·20 respectively. The component responsible for the faster-running spot was separated from N-acetylgalactosamine on washed Whatman No. 31 thick paper by the usual method of band chromatography with marginal vertical strips to indicate its position. From a 25 mgm. sample of the N-acetylgalactosamine preparation applied to the paper, approximately 2·5 mgm. of the new component was separated. No N-acetylgalactosamine could be detected in the separated material by paper chromatography.

The absorption spectrum of the chromophore formed by the sugar after treatment (4 min., 100° C.) with 0·05 *N* sodium carbonate and addition of the *p*-dimethylaminobenzaldehyde reagent was identical with those given by N-acetylgalactosamine and N-acetylglucosamine[2]. The optimum heating period for maximum colour production under the conditions employed was 4 min., and the sugar resembled N-acetylgalactosamine in that it gave only about one-fifth of the colour given by an equal weight of N-acetylglucosamine[2].

The separated sugar was deacetylated by hydrolysis with 0·5 *N* hydrochloric acid for 6 hr. at 100° C. The hydrolysate was analysed on columns of 'Zeo-Karb 225' resin by a modification of the method of Gardell[3]. Columns were developed with 0·33 *N* hydrochloric acid which separated not more than 2 per cent of galactosamine from a slower running component (Fig. 1). When glucosamine and galactosamine were added to the hydrolysate, three components could be separated completely from one another, emerging in the order, glucosamine, galactosamine and the new amino-sugar. The absorption

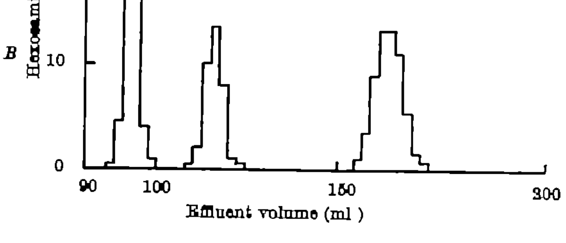

Fig. 1. Separation of amino-sugars on a column of 'Zeo-Karb 225' resin. *A*, a new amino-sugar (talosamine); *B*, the same sugar with added glucosamine and galactosamine

spectrum of the latter on reacting with alkaline acetyl acetone and the *p*-dimethylaminobenzaldehyde reagent[4] was identical with those given by glucosamine and galactosamine.

Although the amino-sugar when deacetylated could be distinguished from glucosamine and galactosamine using columns of 'Zeo-Karb 225', this was not possible on paper chromatograms developed in butanol/pyridine/water or *s*-collidine, where it occupied a position identical with that of glucosamine. When phenol/ammonia was employed as solvent, the sugar could not be distinguished from galactosamine, and in butanol/acetic acid/water (4 : 1 : 5) it did not separate from the glucosamine–galactosamine position.

Examination by paper chromatography of the products of its oxidative deamination with ninhydrin[5] revealed the presence of a pentose which was neither arabinose nor ribose but which occupied a position close to that of lyxose or xylose. Since lyxose and xylose are not widely separated in the solvent systems employed, that area of the chromatogram corresponding to the lyxose–xylose region was eluted and the eluate examined by paper electrophoresis using a 0·05 *M* borate buffer (*p*H 9·6). Under these conditions, lyxose and xylose separated completely and the pentose formed by the amino-sugar occupied a position identical with that of lyxose. It is therefore concluded that the sugar is the epimer of galactosamine, namely, 2-amino-2-deoxy talose, and that the preparation of N-acetylgalactosamine used contained some N-acetyltalosamine. Since talosamine has not been detected in certain other samples of galactosamine isolated from sheep tracheal cartilage and which had not been N-acetylated, it cannot be assumed that the sugar occurs naturally.

The behaviour of talosamine on paper chromatograms using a variety of solvent systems indicates that a spot in the position of glucosamine or galactosamine is insufficient evidence for the identification of these sugars. A satisfactory method of analysis is the use of columns of 'Zeo-Karb 225' resin with 0·33 *N* hydrochloric acid as eluant, combined with a chromatographic examination of the N-acetylated amino-sugars on paper.

Since this work was completed, Muir[6] has described the presence of talosamine in acid hydrolysates of chondroitin sulphate isolated from hyaline cartilage. The unexpectedly low *R*(glucose) value recorded by Muir[6] for this sugar in butanol/acetic acid/water (4 : 1 : 5) disagrees with the present results, since talosamine obtained from its N-acetylated derivative failed to separate from glucosamine and galactosamine in this solvent system.

I wish to thank Prof. W. T. J. Morgan for gifts of galactosamine and N-acetylgalactosamine. The technical assistance of Miss Joan Pleasants is acknowledged.

Isolation of 3 : 4-9 : 10-Dibenzopyrene from Coal-Tar

By fractionation of coal-tar on alumina, Berenblum and Schoental[1] demonstrated that the fraction preceding and that following the one containing 3 : 4-benzpyrene were carcinogenic to rodents though free from spectrographically detectable amounts of 3 : 4-benzpyrene. Fractional crystallization of picrates from the fraction following the one containing 3 : 4-benzpyrene gave, among others, reddish-brown needles melting at 160–189° C. These picrates were decomposed by chromatography on alumina, and after repeated crystallizations from various solvents yielded yellow glistening scales, melting with some softening at 280° C.

This compound, giving with concentrated sulphuric acid a green solution with red fluorescence, has recently been re-examined and identified as 3 : 4-9 : 10-dibenzopyrene by its fluorescence spectrum showing main bands at 432 and 460 mμ in cyclohexane, identical with those of an authentic specimen, and by the absence of depression of its melting point when mixed with 3 : 4-9 : 10-dibenzopyrene[2,3].

I am indebted to Dr. E. Clar, Chemistry Department, University of Glasgow, for a specimen of authentic 3 : 4-9 : 10-dibenzopyrene and to Mr. M. J. Lyons, Department of Cancer Research, Royal Beatson Memorial Hospital, Glasgow, for the fluorescence spectra.

Conversion of Glycogen to Sorbitol and Glycerol in the Diapause Egg of the *Bombyx* Silkworm

In the course of biochemical studies[1] on the embryonic diapause of the *Bombyx* silkworm, it has been shown that the glycogen content of the egg decreases markedly at the onset of diapause and reaches the lowest level at about thirty days after oviposition. When diapause is broken by cold treatment, glycogen increases progressively even at low temperature and regains the initial level almost completely. Pursuing the fate of glycogen during the diapause period, I have found that it is not consumed as an energy source, but it is converted to other substances including the following: sugars and their polymers, fat, lactic acid, gluconic acid and other organic acids such as Krebs cycle members, phosphoric esters and amino-acids.

It has been found that the main bulk of glycogen is converted into two kinds of polyhydric alcohols, namely, sorbitol and glycerol. Fig. 1 shows the chromatogram of the polyhydric alcohols extracted from the diapause eggs and Table 1 gives the R_F values of these alcohols in various solvents. It is apparent from the chromatogram reproduced as Fig. 1 that the marked decline of glycogen at the onset of dia-

Table 1. R_F VALUES OF TWO SPOTS OF SAMPLE FROM THE DIAPAUSE EGGS, AND THOSE OF VARIOUS POLYHYDRIC ALCOHOLS AND ASCORBIC ACID

	Solvent *A*	Solvent *B*	Solvent *C*	Solvent *D*	Solvent *E*
Sample from diapause egg	0·54 0·30–0·31	0·51 0·26	0·60 0·35	0·26 0·06	0·11 Origin
Glycerol	0·54	0·51	0·60	0·25	0·11
d-Sorbitol	0·31	0·26	0·35	0·06	Origin
d-Mannitol	0·33	—	—	—	—
Inositol	0·18	—	—	—	—
Ascorbic acid	0·44	—	—	—	—

Two spots of sample from the diapause eggs are strongly positive for ammoniacal silver nitrate alone and completely negative for both aniline hydrogenphthalate and orcinol reagents. This fact indicates clearly that the substances in question are not sugars, but are polyhydric alcohols. Solvent *A*: butanol/acetic acid/water (4 : 1 : 2); *B*: butanol/ethanol/water (4 : 1 : 2); *C*: butanol/pyridine/water (3 : 2 : 1·5), *D*: ethyl acetate/acetic acid/water (3 : 1 : 3); *E*: chloroform/ethanol (8 : 2)

pause is coupled with the formation of sorbitol and glycerol, only traces of which are found before and after diapause. Quantitative analysis has been carried out, based upon the oxidation with periodate of the alcohols eluted from the filter paper and subsequent colour reaction with chromotropic acid[2]. The results indicated that the highest contents of sorbitol and glycerol found during the diapause period amounted to 23 mgm. and 11 mgm. respectively per gram of fresh eggs, thus accounting quantitatively for the decrease of glycogen. In other words, glycogen is converted completely into these two alcohols during the diapause period. So far as I am aware, the presence of sorbitol in animal tissues has not been reported hitherto or the accumulation of glycerol to such an extent, except in some micro-organisms under special conditions.

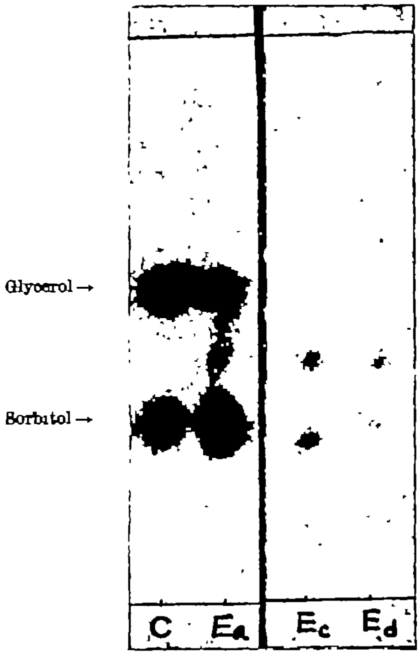

Fig. 1. Chromatogram of polyhydric alcohols found in the *Bombyx* silkworm egg. Detection of spot: ammoniacal silver nitrate. Solvent: butanol/acetic acid/water (4 : 1 : 2). *C*. sorbitol and glycerol as control; E_a: sample from eggs during diapause period (minimal glycogen stage); E_c: sample from the eggs just before onset of diapause (12 hr. after oviposition, maximal glycogen stage); E_d: sample from the eggs after termination of diapause (glycogen maximum again)

A detailed account of this work and related experiments will be reported elsewhere.

C_{12}-Hydroxylation of Digitoxin

USING paper chromatographic methods it has been shown that, following digitoxin administration to rats, the urine contains small amounts of unchanged digitoxin together with larger quantities of two cardio-active metabolites previously designated metabolites *C* and *G* [1,2]. Human urine collected for 12 hr. from normal adults after an oral dose of 1 mgm. of digitoxin has now been found to contain some unchanged digitoxin as well as apparently larger quantities of two metabolites. The two metabolites when eluted from paper and rechromatographed using two systems of paper chromatography could not be separated from metabolites *C* and *G*.

Furthermore, metabolite *G* could not be separated from the glycoside digoxin (12-hydroxydigitoxin) by paper chromatography on formamide paper using three different developing solvents (benzene, chloroform, butanol[1]; tetrahydrofurane, chloroform[3]; and methyl *iso*butyl ketone, *iso*propyl ether[4]) or by the reversed phase systems I and II of Tschesche, Grimmer and Seehofer[5].

After elution from paper, metabolite *G* was refluxed with 0·5 per cent hydrochloric acid, extracted with chloroform, and yielded a substance which was indistinguishable from digoxigenin when compared on two systems of paper chromatography. Furthermore, this hydrolytic product when dissolved in concentrated sulphuric acid gave an ultra-violet absorption spectra with peaks at 390 and 470 mμ, similar to digoxigenin under the same conditions. This spectrum was distinctly different from that of 11-hydroxy digitoxigenin (sarmentogenin) and of epi-sarmentogenin taken in sulphuric acid.

Biosynthetically labelled radioactive carbon-14 digitoxin[6] diluted with non-radioactive digitoxin (2 μgm./gm.) was injected intraperitoneally into rats, the urine metabolites separated on formamide paper strips[1], and then eluted from the paper with methanol. Non-radioactive digoxin (10 mgm.) was added to the eluate of the metabolite *G* area and the recovered digoxin recrystallized to constant specific activity in order to confirm radiochemical purity. Specific activities of 22·6, 20·8, 22·0, 21·0 and 20·4 d.p.m. per mgm. were obtained on five separate recrystallizations.

From these results it appears that when digitoxin is administered to rats or to humans some of it undergoes hydroxylation at C_{12}. Further confirmation of this was obtained by showing that metabolite *B* previously found in rat urine after digoxin administration[7] cannot be separated by paper chromatography from metabolite *C* present in human and rat urine after digitoxin administration.

It is hoped to publish this work in detail elsewhere. One of us (S. E. W.) wishes to thank the Pharmacology

Cytochrome Composition of Some Strains of *Streptomyces*

SMITH[1] has discussed the bacterial cytochromes in relation to each other and in comparison with those from yeast and mammalian sources. Her review serves to emphasize the variations existing among the bacteria, and the fact that generalizations concerning the functions of the various cytochromes are difficult to make. Since information concerning even the existence of cytochromes in Streptomycetes is meagre[2], it was felt that a spectrophotometric survey of the general cytochrome composition of various strains would provide a useful basis for more complete investigations of a physiological nature and contribute to the microbial cytochrome picture in general. Furthermore, the activity of Streptomycetes as prolific producers of antibiotics and as producers of vitamins makes a better understanding of their physiology of considerable interest. In this regard, various investigations have shown that iron is required in media used for antibiotic production by Streptomycetes[3], and a recent investigation of the effect of trace metals on their growth revealed a striking beneficial effect of iron on each of eight organisms examined[4]. These results and the importance of iron in respiratory pigments suggested the likelihood that cytochromes were present.

Cultures were grown in 100 ml. yeast dextrose broth (yeast extract, 10 gm./l.; dextrose, 10 gm./l.; *p*H 7·5) in 250-ml. Erlenmeyer flasks and incubated on rotary shakers at 28° C. until heavy growth was evident. The time varied from two to seven days, depending on the strain. Cells were harvested by centrifugation and washed with 0·9 per cent saline.

One species, *Streptomyces fradiae* strain No. 3535, was also grown in *NZ* amine medium (2·5 per cent *NZ* amine – Sheffield Farms casein hydrolysate, 1·0 per cent meat extract, tap water, *p*H 7·0) to investigate the possible effect of a change in composition of medium on the type of cytochromes present.

Homogenates were prepared by a modification of a method used by Nielands[5] for the extraction of cytochrome *c* from *Ustilago sphaerogena*. Cells were suspended in distilled water to form a thick slurry and adjusted with sodium hydroxide to *p*H 10·5. They were then disrupted by sonic vibration for 10–12 min. in a 'Raytheon' sonic oscillator (9 kc./s.).

* Strain numbers are those of the Institute of Microbiology, Rutgers University.

† These results are from cells grown in *NZ* amine broth, all others from cells grown in yeast dextrose broth.

In most cases it was possible to obtain a difference spectrum directly from the homogenate without centrifugation by reducing one sample with sodium hydrosulphite and comparing it to an unreduced standard. Spectra were obtained with Beckman Model *DU* or Model *B* spectrophotometers, or a Cary Model 14*M* recording spectrophotometer. In every case the alpha and beta peaks could be observed as bands with a hand spectroscope in the homogenates as well as in whole-cell suspensions.

The results of the survey are presented in Table 1. To increase the accuracy of the comparison, the values presented were all obtained on the Cary recording spectrophotometer. Three conclusions can be drawn. (1) Two groups of cytochromes are clearly represented. A *b* type is indicated by the 558–563 mμ alpha peak; a *c* type by the 550–552 mμ alpha peak. The gamma peaks of *b* and *c* types show up as distinct entities in only two species. (2) The cytochrome composition was essentially the same in the different strains of *S. fradiae*, *S. lavendulae* and *S. griseus*. The 468 mμ peak in *S. griseus*, strain 3570, is unidentified. (3) Cultivation of *S. fradiae* in two different media did not alter the cytochrome composition.

The results indicate that the cytochrome composition of Streptomycetes is similar to that of other micro-organisms in spite of the fact that cytochrome oxidase has not been observed in alkaline homogenates, neutral homogenates, or whole-cell suspensions. They do not permit any choice between the possibilities that the methods employed were not sensitive enough to detect low concentrations of cytochrome oxidase or that the Streptomycetes have some other means of linking the cytochromes with oxygen.

Although the composition of the cytochrome from *S. fradiae* remained the same in two different media, it is possible that different environmental changes might result in a change of cytochrome. For example, changes in the cytochromes have been reported as a result of variations in oxygen tension, metal composition of the media, or the passage of cells from a resting state to a growing state[1]. Even if changes can occur, the fact remains that, under the conditions described, *S. fradiae* was able to grow well in two different media without the presence of any apparent cytochrome *c* pigments. The other strains in which no *c* was detected also grew well.

That five strains have only *b* type cytochromes is of considerable interest since *b* cytochromes are autoxidizable and might conceivably react through a path to oxygen other than through *c* and a_3. The *b* cytochrome of *S. fradiae* 3535 has been partially purified and characterized[6].

Removal of Internally Deposited Radiocerium by the Use of Chelating Agents

IN recent years, polyamino-acids, and ethylenediaminetetra-acetic acid in particular, have proved of substantial value as therapeutic agents in cases of poisoning by radioactive or stable metals. However, the compounds hitherto investigated are of very poor efficiency when treatment is delayed[1], and are unable to prevent the deposition of certain elements, such as cerium[2] or lanthanum[3], in the skeleton, even when administered in most favourable conditions. In view of these findings, experiments on several other chelating substances were performed in the hope of obtaining more effective agents.

Albino rats averaging 130 gm. were injected intravenously with tracer amounts of cerium-144/praseodymium-144. The chemicals to be tested were administered intravenously in series 1 and 2 simultaneously with the radiocerium and in series 3 by intraperitoneal route 3–5 min. after incorporation of radiocerium. The animals were killed after 48 hr., the organs processed and their cerium-144 content determined.

As shown in Table 1, the bulk of the agents tested proved to be either of low efficiency or ineffective with regard to the fixation of radiocerium by the skeleton. The administration of substances I, IV, VII caused even a higher retention significant at the 20, 1 and 5 per cent level respectively, in spite of the relatively high dosage. A substantial minimization of the skeletal deposition was achieved only by the two substances X and XI, possessing oxygen as heteroatoms, as well as by the condensed polyphosphate VIII, acting according to Thilo[4] as a soluble ion-exchanger. It should be mentioned that the polyphosphate is also effective, though only slightly, in removal of radiostrontium[5].

In series 4 the chelating agents were administered on the fifth, tenth and sixteenth day following the incorporation of radiocerium. The urinary excretion during this period occurs at an approximately constant level of 0·08–0·14 per cent per day. Urine and faeces were collected separately before and after administration of the agents, and their radioactivity assayed. The substances VII, VIII, III were ineffective, I, II, as well as zirconium citrate (450 mgm./kgm.), caused an increase of the urinary excretion by a factor of 2–3, substance IV by a factor of 6–7, and substance X by a factor of 10. The most striking effect was obtained for substance XI, which raised the urinary excretion from the base level up to as much as 4–5 per cent per day. The exceptionally high efficiency of diaminodiethylether tetra-acetic acid in early as well as in delayed treatment makes this substance seem worthy of more detailed investigation. Experiments now in progress will be reported later.

Table 1. PERCENTAGE OF CERIUM-144 DOSE ADMINISTERED AND MEAN STANDARD ERROR IN THE RELEVANT ORGANS
Each experimental group comprises 4–5 rats. The dosage (μmoles/rat) if not otherwise stated was 90 in series 1 and 2, 275 in series 3

Action of Blue Light on the Germination of Seeds

THE mutually reversible influence of red and far-red radiation on seed germination is to-day a well-established fact. The role of other regions of the spectrum is less certain. Conflicting results, for example, have been reported on the action of blue light on germination (see review in ref. 2). In the present work we have investigated the effect of light in this part of the spectrum, and especially the change of this effect with time elapsed since the start of imbibition. It is known that even for red light the sensitivity of the seeds changes with the time[1]. The seeds used were lettuce seeds var. Grand Rapids. The methods of imbibition, counting and irradiation were as in ref. 3. Spectral bands were isolated using the following filters:

Table 1

	Filter	Light incident on seeds (ft.-candles)
(1)	Corning glass No. 430 (3 mm.)	30
(2)	Corning 5113 (3·35 mm.) + Corning 3389 (2·0 mm.)	1·7
(3)	Chance's glass *OBR* (3 mm.) + *OGRI* (3 mm.)	10·5

The light transmission through these filters is shown in Fig. 1. Apart from a very slight (1 per cent) transmission at about 750 mμ by filter 1, this filter transmits a broad band between 350 and 590 mμ. Filter 2 transmits a very narrow band, with maximum at 430 mμ, the (asymmetrical) half-width being − 10 and + 25 mμ only. Filter 3 isolates a band between 450 and 590 mμ. These two filters show no perceptible transmission in the red or far-red region. Fig. 2 shows the results obtained. All three filters show identical behaviour in that only after about 10 hr. from imbibition do they exhibit a noticeable promoting effect on the percentage of germination. Filter 1 has a maximum effect after 13 hr., raising the percentage of germination by 46 per cent. This cannot be due to the small red or far-red component, since these lights, on the contrary, show decreased effects at these stages of the germination process. This is confirmed by the similar behaviour of filters 2 and 3. In particular, filter 2, which isolates a very narrow band of blue light, exhibits an inhibitory effect on germination during the first 6 hr., changing to a promoting effect only after 10 hr. The extent of this inhibition in comparison with that caused by the far-red component is shown in Table 2, which gives the percentage germination of seeds germinated: (1) in darkness; (2) illuminated 30 min. after imbibition with far-red; or (3) with filter 2 for 3 min.

Table 2

(1)	(2)	(3)
41 ± 4	28 ± 5·6	29 ± 2·2
33·5 ± 3·2	24·5 ± 5·8	25 ± 3·5

We find thus that the blue region of the spectrum, where certainly different absorption bands are responsible for the photo-response, nevertheless exhibits effects of promotion and inhibition of germination similar to that of red or far-red light.

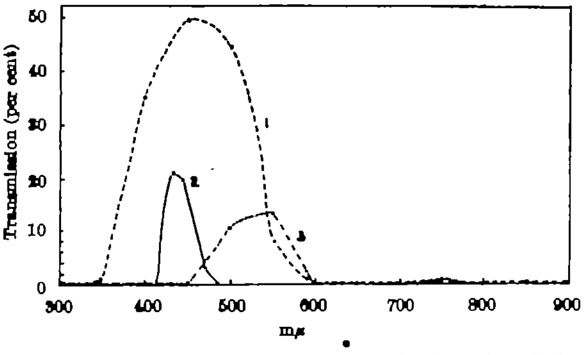

Fig. 1. Transmission of filters 1, 2 and 3 in the different spectral regions

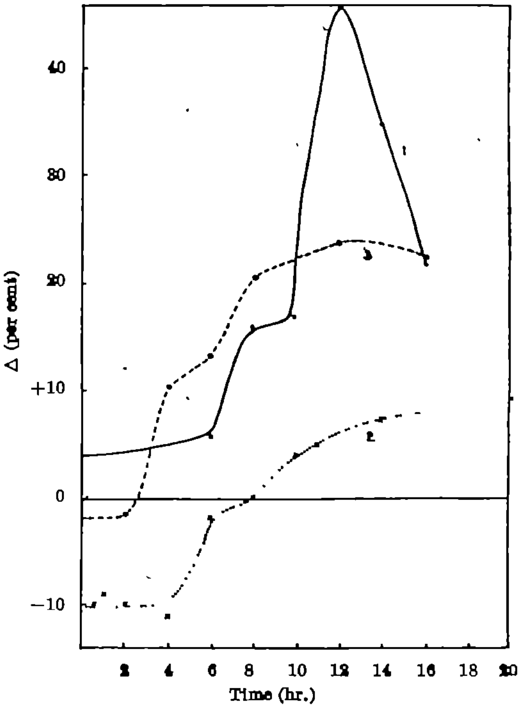

Fig. 2. Germination of lettuce seeds after illumination with filter 1 (1 min.), filter 2 (5 min.) and filter 3 (8 min.) at different times after the start of imbibition. The ordinate gives the difference between the percentage germination of the illuminated seeds and that of seeds kept in darkness. The zero line represents the percentage germination in darkness

However, the dependence on time of the photo-reaction for blue light is quite different from that for red or far-red illumination.

Effect of Ultra-Violet Radiation on the Respiration-Rates of Tobacco Leaves, and its Reversal by Visible Light

Bawden and Kleczkowski[1] have shown that injury to the leaves of higher plants by exposure to ultra-violet light is prevented by subsequent exposure to visible light, and have related this effect to the phenomenon of 'photo-reactivation' or 'photo-reversal'. During an investigation of the effect of irradiation on the establishment of virus infection in tobacco leaves evidence of a similar effect on leaf respiration has been obtained, and further investigation produced the results presented below.

Tobacco leaves were exposed to ultra-violet radiation of a wave-length of 2537 A. at an intensity of 870 μW./cm.^{2} for 1–4 min.; they were then detached and placed in the dark and their respiration-rates measured for 10 hr. with an infra-red carbon

dioxide analyser. Table 1 shows that the respiration-rates increased with increasing exposure time, until, after 4 min. exposure, the rates were increased by 20 per cent above the respiration-rates of comparable non-irradiated leaves.

To test whether this effect was reversed by visible light, leaves were irradiated for 5 min., and then half of them were kept in the dark for 2 hr. while half were exposed to full sunlight in a glasshouse. A similar number of non-irradiated leaves were given the same treatments as controls. Respiration measurements were begun at the end of the 2-hr. period, each experimental run involving the comparison of the respiration-rates of four leaves from each of the four treatments, over the same 10 hours. Table 2 shows that the respiration-rates of leaves irradiated and then kept in the dark were again 20 per cent higher than rates for non-irradiated leaves also kept in the dark, but the rates for irradiated leaves exposed to sunlight were not significantly higher than those of non-irradiated leaves which had also been exposed to sunlight.

Table 2. THE EFFECT OF EXPOSURE TO VISIBLE LIGHT FOR 2 HR. ON THE RESPIRATION OF TOBACCO LEAVES AFTER IRRADIATION WITH ULTRA-VIOLET FOR 5 MIN.

Means over 10 hr. in mgm./CO_2/hr./gm. dry matter

Ratio $\frac{\text{Irradiated}}{\text{Non-irradiated}}$	1·07		1·21

No. of determinations represented by means = 10

Bawden and Kleczkowski suggest that changes in leaf-cell components caused by ultra-violet radiation are reversed by visible light, or that light stimulates synthetic mechanisms to produce new components to replace those damaged. The latter suggestion now seems unlikely, because increased respiration would be expected to accompany such increased metabolic activity and no increase in respiration-rate was observed. Ultra-violet radiation must initiate a process or processes which is capable of proceeding in the absence of ultra-violet, as the effect of the disturbance to cell metabolism is still detectable 10 hr. after irradiation, but darkness is necessary for the reaction to proceed.

Infection with tobacco mosaic virus increases the respiration-rates of tobacco leaves immediately after inoculation[2], and ultra-violet irradiation increases the respiration-rate immediately after treatment, the latter increase being four times the former. If both effects were due to action on the same cell component, the more rapid rates of change indicated by the larger energy expenditure after irradiation may mean that reduced supply of this component is responsible for the prevention of virus synthesis in irradiated leaves. The mechanism by which visible light counteracts this effect remains obscure.

Rapid Estimation of the Areas of the Leaves of Crop Plants

FOR the physiological analysis of plant growth, estimates of the total leaf area per plant are required, and this may involve the determination of the areas of large numbers of leaves. Freeman and Bolas[1] have described a method for the construction of a measuring grid from which the areas of leaves may be read directly, providing that the leaf-shape approximates closely to an ellipse, as does the shape of the apple leaves used by them.

It has been found possible to modify this method for use on leaves which are not elliptical, and a satisfactory grid has been constructed for sugar beet leaves. Further modification is possible for any leaves for which there exists a convenient pair of dimensions linearly related to area, and in which the leaf shape is either independent of size or changes regularly with size. If the leaves are asymmetrical about the horizontal axis as in Fig. 1, two convenient measurements such as A and B which act as co-ordinates to some definable point on the leaf, such as P, the point of maximum width, are measured and the area of the leaf is measured with a planimeter. This is repeated for as many leaves as practicable over as wide a range of leaf-size as possible.

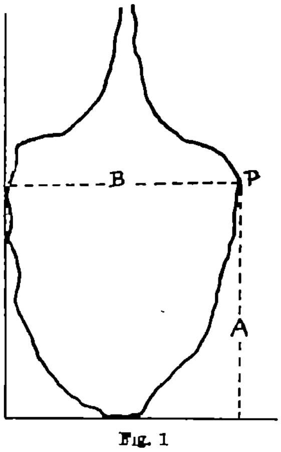

Fig. 1

For sugar-beet leaves, a linear regression of leaf area on AB accounted for 99 per cent of the variance of leaf area (regression coefficient $= b = 1·05 \pm 0·013$). The leaf area is therefore equal to b (AB). The co-ordinates of P are A, B, and the area represented by the point is AB units. Therefore, for P to indicate the leaf area in sq.cm. on a grid constructed in the manner described by Freeman and Bolas, the area of each square of the grid must be $1/b$ sq.cm. and the linear dimensions of the grid must be $\sqrt{1/b}$ cm. The grid constructed for sugar-beet leaves contained squares each of 0·97 cm. sides, so the figure at point P of each leaf placed on the grid represented the area of that leaf in sq.cm. To test the method the areas of 155 leaves were measured by the grid and by planimeter, the areas of the leaves varying from 1 to 400 sq.cm. Linear regression of the planimeter areas against the grid areas accounted for 99·2 per cent of the variance of the areas. This method is likely to be more accurate than the rating methods at present used when the leaf areas must be estimated without destroying the leaves.

Successful Crossing in the Genus *Lathyrus* through Stylar Amputation

INTERSPECIFIC hybridization in the genus *Lathyrus* has been attempted by several workers with little success. Barker[1] obtained viable, partially fertile hybrids from the cross *L. hirsutus* × *L. odoratus*. Taylor[2] claimed to have produced seeds by crossing *L. odoratus* with *L. pratensis* reciprocally. It has not been possible to repeat this cross. Senn[3] reported failure in 458 attempts at intercrossing seventeen species of *Lathyrus* and *Pisum sativum*. Marsden-Jones[4] successfully crossed *L. rotundifolius* with *L. tuberosus*. In this Department viable seeds have been produced from the following crosses: *L. cicera* × *L. sativus* (Saw Lwin*), *L. clymenum* × *L. ochrus* (Saw Lwin*), *L. clymenum* × *L. articulatus*—reciprocally (Davies), *L. articulatus* × *L. ochrus* (Davies), *L. hirsutus* × *L. odoratus* (McWhirter*), *L. odoratus* × *L. hirsutus* (Davies), *L. sylvestris* × *L. latifolius* (Ellis*).

The cross *L. hirsutus* × *L. odoratus* of Barker has been successfully repeated in this Department without difficulty. Some reciprocal crosses were attempted between 1951 and 1955 but were unsuccessful.

The reasons for failure in interspecific hybridization attempts have been discussed by Blakeslee[5], and methods employed to overcome barriers to crossability have been reviewed by Maheshwari[6]. Lack of success in the cross *L. odoratus* × *L. hirsutus* could be due to the greater style-length of *L. odoratus* (10 mm.) as compared with *L. hirsutus* (4 mm.). Style-length differences contributed to the failure of interspecific crossing attempts in the genus *Datura*[5].

A modification of the technique of Buchholz *et al.*[7] involving complete amputation of the female parent style was used in crossing *L. odoratus* with *L. hirsutus*, and several hybrids were produced. The best results were obtained by pollination on the cut stump after all the style was removed, though after removal of 4 mm., 6 mm. and 8 mm. portions, fertilization did sometimes take place. Grafting *L. hirsutus* styles on to the ovaries of *L. odoratus* was successfully effected, but showed no advantage over direct pollination on the cut stump.

For routine crossing and to avoid emasculation damage, a modification of Doak's soda-straw method[8] for crossing *Gossypium* was found to be useful. Pieces of the culms of various species of grass were fitted down over the styles of unopened flowers, excluding the anthers and with one end protruding from the keel. When the flower had opened pollen was pushed down the culm with a tightly fitting glass rod on to the stigmatic surface. This method may have wide application in work with other genera.

This work was undertaken during the tenure of an Agricultural Research Council Research Studentship.

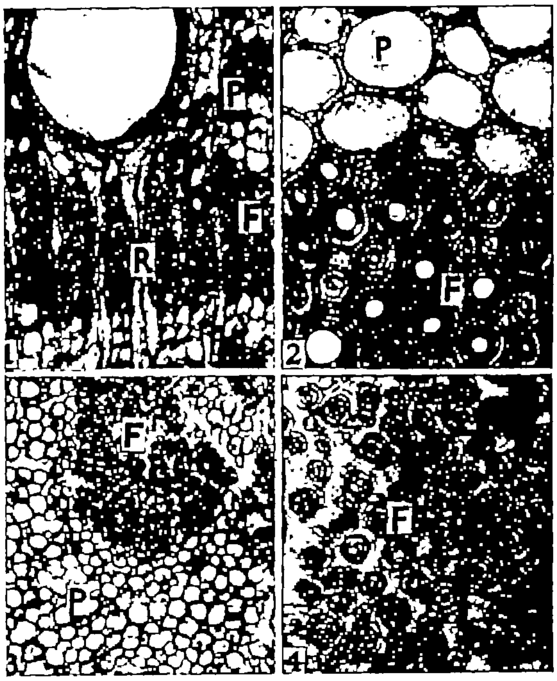
Difference in the Behaviour of Tissues in Ancient Plant Remains and during Chemical Treatment

ALTHOUGH considerable work has been done on the cell wall structures of ancient and buried woods[1] and their degradation[2] from chemical, physical and botanical aspects[3], little attention has so far been paid to the differential behaviour of the main tissues of such woods. While studying the minute anatomy of fossil woods and buried woods, we noted the peculiar behaviour of the two important tissues of the dicotyledonous woods. During long submersion of wood in water or soil, parenchyma cells and rays are usually found to retain their original structure better than the fibres (Fig. 1). This was reported by two of us (K. A. C. and S. S. G.), but no definite reason for such behaviour could be put forward except the nature of pits on the walls of fibres, vertical parenchyma cells and wood rays[4]. The main obstacle to chemical investigation has so far been the difficulty of obtaining pure samples of parenchyma and fibres from fresh woods. Recently, while working on bamboo, it has been possible to separate mechanically its parenchymatous and prosenchymatous tissues. This led us to think that it might be worth while analysing chemically these pure tissues and at the same time examining them microscopically at different stages of delignification, with the view of getting a clearer picture of the nature of the cell wall.

Chips of bamboo (*Dendrocalamus strictus* Nees) were delignified in a pressure autoclave by the conventional sulphate method for various periods. In this method, delignification was carried out with a solution containing sodium hydroxide and sodium sulphide in the ratio of 2 : 1 for various periods up



All are transverse sections. (1) Buried wood (*Dalbergia latifolia* Roxb.) of thousand years (× 120). (2–4) *Dendrocalamus strictus* Nees. (2) Untreated fibres and parenchyma (× 300). (3) After 5 hr treatment (× 45). (4) Fibres of (3) highly magnified (× 300), cf. (2) and (4) and note difference in the structure of fibre wall. *F*, fibres; *P*, parenchyma; *R*, rays

Table 1. ANALYSIS OF TWO TISSUES IN BAMBOO AND IN THE UNBLEACHED PULP AT DIFFERENT PERIODS OF DELIGNIFICATION AND THEIR LIGNIN CONTENT

Period of delignification including 1 hr. to bring to 162° C. (hr.)	Yield on bamboo		Lignin content	
	Fibre (per cent)	Parenchyma (per cent)	Fibre (per cent)	Parenchyma (per cent)
Raw chips	64·3	35·7	28·8	27·4
1·0	37·6	17·9	8·3	11·6
2·0	32·2	17·3	4·5	7·2
3·0	33·1	15·8	3·6	6·4
4·0	33·4	14·2	2·9	5·9
5·0	33·6	14·1	2·8	5·5
6·0	32·4	14·6	2·5	5·6

to a total of 6 hr., including 1 hr. taken to raise the contents to 162° C., the maximum temperature of delignification. The material (chips) to liquor ratio was 1 : 5. After each reaction the delignified chips were carefully and repeatedly washed with distilled water by diffusion, so that the anatomical structure was not disturbed. A sample of cooked chips was then taken out, properly embedded and cross-sections cut with a microtome. The rest of the delignified chips were macerated into separate tissue entities by mechanical disintegration. From a very dilute (0·1–0·05 per cent) slurry of this pulp in water, the fibre and parenchyma tissues were separated by hand-sieving successively on screens of 20, 120 and 200 mesh. The fibres were largely retained on 20 and 120 mesh. The fine parenchyma cells passed out finally through the 200 mesh. The tissue samples were checked under the microscope for purity and if found impure were re-screened. The separated tissues in their unbleached state were analysed for lignin. Fibres and parenchyma tissues in the original bamboo chips (untreated) were also estimated and their lignin content determined.

The results given in Table 1 show that the two tissues (Fig. 2) behave differently to delignification, the fibres reacting faster than the parenchyma cells. After 6 hr., the lignin in fibres is reduced to 2·5 per cent, whereas in parenchyma cells it is 5·6 per cent. The anatomical structure of these tissues after treatment for 5 hr. reveals that the parenchyma cells are still intact and adhere to each other (Fig. 3), while the fibres have undergone considerable disorganization and are individually separate from each other (Fig. 4). Thus it will be seen that there is a difference in the ability of these two tissues to resist delignification. This may to some extent explain why the fibres disorganize and disintegrate more quickly than the parenchyma cells in fossil and buried woods.

It is possible that work on the physical structure of these cells may also throw some light on this problem; this aspect we intend to take up.

Germination of Oospores of *Pythium mamillatum* in Response to Exudates from Living Seedlings

THE exudation of chemical substances from roots of higher plants, and the effect of these substances in increasing general microbial activity in the immediate vicinity of roots growing in soil (that is, the rhizosphere effect), have now been fairly well established. Nevertheless, the possible function of these exudates in the etiology of root disease, bringing about the germination of spores or propagules of root-infecting fungi resting in the soil, has received less attention than it undoubtedly merits. The recent interest shown in this subject[1,2] has prompted me to make a preliminary report of some similar studies now in progress with oospores of *Pythium mamillatum* Meurs.

Glass-fibre tape[3], 1·5 cm. in width, was divided down the middle, and cut into pieces approximately 5 cm. in length. After sterilization, these sections were placed on oat agar plates which were inoculated with *P. mamillatum*, and incubated at 25° C. for one month. At this stage, sufficient mature oospores had been formed in the interstices of the tapes for the purposes of the experiment, and few hyphæ remained. Microscopic observation of oospores on this material was facilitated by staining in phenolic rose bengal[4] for 1 min.

Tapes stained and examined after being buried for 3 days beneath 2–5-day old turnip seedlings in garden soil consistently showed that oospore germination had occurred. Oospores on tapes placed in similar soil in the absence of seedlings did not germinate. Only scattered areas on each tape were affected, suggesting that stimulation took place in close proximity to the roots themselves, a finding similar to that of Jackson[1]. Drechsler[5] has reported the production of zoospores directly from oospores of *P. mamillatum*, but during this investigation, germinating oospores invariably produced germ tubes.

Attempts to repeat the stimulation in culture have been successful. Oospores on tapes placed in Petri dishes filled with distilled water either failed to germinate at all or else germinated at such a low frequency that it was almost unmeasurable. On the other hand, when turnip seeds were sown in this water and allowed to develop in a normal manner, a striking increase in the frequency of oospore germination was observed even after two days. The stimulation occurred also when direct contact between oospores and seedlings was prevented by a layer of filter paper. Exudates from turnip seedlings have been collected and tested for stimulatory activity. Seeds were surface sterilized, and allowed to germinate and grow in sterilized distilled water for seven days. This water was then concentrated by freeze drying to a final volume one-tenth of the original. Application of this solution to oospores on glass-fibre tapes resulted in a marked increase in germination as compared with distilled-water controls.

The evidence suggests, therefore, that certain water-soluble stimulatory substances are liberated from living turnip seedlings, and have an activating effect on oospores of *P. mamillatum*. The nature of this stimulation remains to be elucidated, but Brown[6] has pointed out that such phenomena may involve a vitamin or phytohormone, or may, more simply, be a direct nutrient effect. The presence of chemical substances pertaining to both these categories has already been reported in root exudates. West[7] found biotin and thiamin in exudates from flax roots, and Fries and Forsman[8] detected several nucleic acid derivatives in pea root exudate. The latter group of compounds might well play a considerable part in stimulating resting bodies such as oospores in which both meiotic and mitotic nuclear divisions generally precede, or coincide with, germination. On the other hand, Rovira[9] has shown that fructose and glucose are exuded by pea and oat roots, and there are several reports of amino-acid material in root exudate. Both amino-acids and sugars, either singly or in conjunction, could sufficiently increase the nutrient level in the immediate vicinity of roots to cause germination of resting spores. Moreover, this latter effect, if operative, might apply more particularly to unspecialized parasites with a wide host range; more specific relationships between host root and resting spore might be expected in the case of specialized root-infecting fungi.

My thanks are due to Prof. C. W. Wardlaw for supervising this work, and to Dr. D. Park for much helpful criticism. Dr. P. F. Wareing placed certain facilities at my disposal.

The work was carried out during the tenure of an award from the Agricultural Research Council, to which grateful acknowledgment is made.

Expression of Sex in Flowering Plants

IN a recent important review of the literature, Heslop-Harrison[1] has listed external variables which may modify sex-expression in flowering plants. The effects of variations in mineral nutrition, in the light regime and in temperature, of mutilation, grafting and the application of chemicals and hormones on the differential production of pistillate and staminate flowers are described. To this review should be added a body of literature on the effects of parasites which, by affecting differently the development of the gynoecium and the androecium, may influence the ultimate 'sex' of the flower. A curious case occurs in the grass *Glyceria maxima* (Hartm.) Holmb., where a late infection of the inflorescence by the smut fungus *Ustilago longissima* (Sow.) Mayen may transform the ovary into a leafy shoot while the stamens are little affected[2].

The greater part of this literature, however, deals with dioecious species of *Melandrium*, which have furnished the test material for so many other studies of sex-inheritance and expression. Both 'sexes' in these species produce androecial and gynoecial primordia; but usually only one of these develops to maturity. It has long been known that the staminal rudiments of a pistillate plant of *Melandrium* may be caused to develop (while the ovary aborts) as a result of infection by *Ustilago violacea* (Pers.) Fuckel. This change, which is probably the result of hormone production or destruction by the fungus[3], provides information which is not incompatible with the hypothesis developed by Heslop-Harrison[1] that the control of sex-expression depends basically upon local concentrations of auxin. Thus pistillate plants which are not systemically infected develop smutted staminate flowers where the fungus is present but produce unaltered pistillate flowers in parts of the plant which are free from infection[4]. Sometimes, lightly infected parts of a pistillate inflorescence will produce flowers in which, although the stamens are forced into development, the ovary is only reduced in size and still contains fairly well-developed ovules.

Observations and experiments on *Melandrium* and on the nature and effects of infection by *Ustilago violacea* have been reported in many papers by Schopfer and Blumer[5–13] and by me[4,14,15]. I was able to show that sex-linked characters in *Melandrium* may be distinguished from secondary sexual characters by their behaviour following the infection of a pistillate plant[14]. The latter quantitative characters tend to be replaced by their counterparts of a staminate flower, whereas the former, which are unaffected, are usually qualitative (and therefore scarcely likely to be determined by simple hormonal means).

Most important is the ability of the single factor of infection to cause *both* the abortion of the gynoecium and the development of the androecium in a pistillate plant. As I pointed out[14], this argues against there being a qualitative difference between 'female-suppressors' and 'male-promoters' such as have been postulated by Westergaard[16–18] to occupy the differential segment of the *Y*-chromosome in *M. album* (although whether anthers or ovules are fertile when produced probably depends upon other factors in addition). If, as Heslop-Harrison suggests, pistil-development depends upon a high auxin-level and stamen-development occurs when it is lower, both 'female-suppressors' and 'male-promoters' may prove to be inhibitors of auxin production or action.

No work has yet been done on the auxin-levels of infected and uninfected pistillate and staminate plants or parts of plants of *Melandrium*, although this might provide valuable evidence for the evaluation of this hypothesis. As the same fungus exerts a similar aborting effect on the gynoecium in hermaphrodite genera of the Caryophyllaceae while *Ustilago succisae* Magnus has the same action in *Succisa pratensis* Moench, further informative auxin-assays are possible.

Only Werth[19] has reported a feminizing influence of the fungus when a staminate plant of *Melandrium* is infected (except for an early slip by Plowright[20] which was corrected soon after[21]). Probably Werth's material consisted of a 'spontaneous' genetically determined hermaphrodite such as are known to arise occasionally in the dioecious species of this genus[15]. Nevertheless, Schopfer[13] has claimed that the infection of staminate plants may increase the rate at which hermaphrodite flowers are formed on male stocks (although this was surprisingly rapid even in his controls). However, his plants were hybrids between *M. rubrum* (Weig.) Garcke and *M. album* (Mill.) Garcke in which it has been shown[15] that there is a lack of complete balance between the sex-determining genes contributed by each of the parents, resulting in a tendency towards hermaphroditism.

There are at least sixteen families of flowering plants where functionally pistillate flowers are known to occur in species which are usually hermaphrodite. Whether they occur in a gynodioecious or gynomonoecious manner, these pistillate flowers are regularly smaller than the hermaphrodite ones[22]. By contrast, where androdioecism or andromonoecism occurs, the staminate flowers are generally as large as hermaphrodites. In at least six families which show what appears to be evolutionarily recent dioecism, there is a similar contrast between pistillate and staminate flower-sizes. This suggests that, although the separation of the sexes has undoubtedly evolved many times in the phylogeny of the flowering plants, the hormonal control of sex-expression is likely to be a relatively simple and general one and may well be connected with the level of auxin-activity in the developing flower-bud. In at least some gynodioecious members of the Labiatae, the abortion of the anthers is associated with a dwarfing of the plant in all its aerial parts.

Mast Cells in the Epithelium of the Œsophagus

MAST cells in epithelium are considered to be extremely rare, and those who have noted them in this site consider that they have migrated from other tissues[1]. During a study of the structure of the mucous membrane of the œsophagus in the adult cat, we have been impressed by the constant finding of large numbers of mast cells in the epithelium. Basic lead acetate was used as a tissue fixative and metachromasia was demonstrated by staining with azure *A* or with toluidine blue. The mast cells are situated in the basal layers of the epithelium (Fig. 1), and were never observed in the more superficial regions. Although comparative counts have not yet been carried out, it appeared that the epithelium of the cranial two-thirds of the œsophagus contained fewer mast cells than the caudal third where, in any high-power field, as many as seven cells might be found. From the present work, in which the œsophagi of thirty animals have been examined, no evidence can be put forward to suggest that these mast cells appear in the epithelium as the result of migration from the subepithelial tissues, or that they migrate within the epithelium itself.

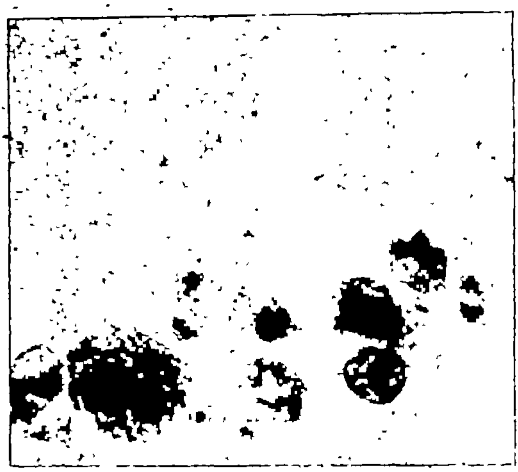

Fig. 1. Two mast cells in the basal epithelial layer of the œsophagus. (× 1,340)

During the study of wound healing in the mucous membrane of the œsophagus[2], mast cells were not found among the regenerating epithelial cells until after epithelialization had become complete.

The significance of these findings, and of other work now in progress on the distribution of mast cells in different animals of varying ages, will be discussed fully elsewhere.

Latent Infection of Rabbits by Adenovirus Type 5

ADENOVIRUSES were first isolated by Rowe, Huebner, Gilmore, Parrott and Ward[1] from cultures of human adenoids undergoing spontaneous degeneration. The same group of workers[2] observed that these agents can be isolated from a large proportion of adenoids and tonsils after these tissues are grown *in vitro* for a certain time. Attempts to isolate the virus by direct inoculation of tissue homogenates into cultures of susceptible cells usually resulted in failure which was attributed to the presence of virus-neutralizing antibody demonstrated in these tissue homogenates. The process of 'unmasking' of the virus in tissue cultures would be a consequence of dilutions of this antibody as a result of successive fluid changes during tissue cultivation. Similar phenomena have been reported in the study of poliomyelitis[3,4], salivary gland virus[5], influenza[6], psittacosis[7] and typhus rickettsiæ[8], and different mechanisms have been suggested to explain virus unmasking.

By the use of tissue cultures we have been able to demonstrate the persistence of adenovirus type 5 in the spleen of adult rabbits for periods up to 8 weeks after inoculation. In a representative experiment, six rabbits were inoculated intravenously with $10^{5\cdot 2}$ 50 per cent tissue culture doses of the prototype strain of adenovirus type 5. The animals were bled at intervals for measurement of antibody pro-

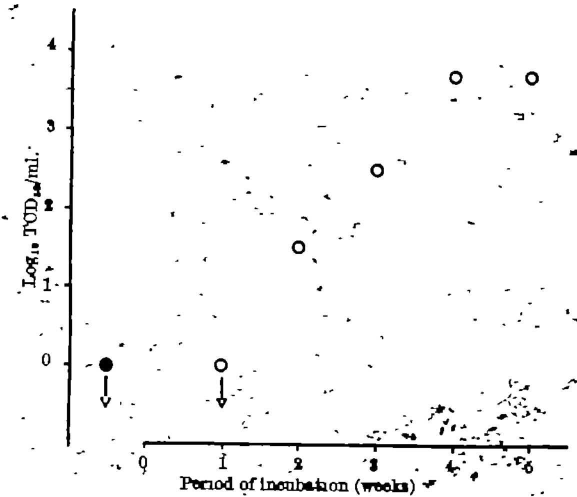

Fig. 1. Virus infectivity levels in spleen homogenate, ●, and in successive fluids obtained from spleen cultures of the rabbit, killed 20 days after inoculation

duction. No clinical signs of disease were observed in any of the rabbits throughout the period of observation. Individual rabbits were killed 3, 6, 13, 20, 27, 41 and 55 days after inoculation and the spleens were removed. Part of the tissue was minced and maintained in Maitland-type cultures with approximately twenty tissue fragments of about 1 mm.^{3} in 2 ml. of a fluid medium consisting of 5 per cent normal horse serum in bovine amniotic fluid. These cultures were set up in universal containers stoppered with rubber bungs and incubated at 37° C. for six weeks with weekly changes of fluid. The remaining spleen tissue was suspended in nine times its volume of broth-saline, crushed in a Ten Broeck tissue crusher, centrifuged and the supernatant of this 10 per cent spleen suspension was preserved. Tissue-culture fluids and spleen suspensions were stored at − 10° C. and tested in HeLa cells for presence of adenovirus. Materials giving rise to cytopathic effect were titrated in HeLa cell cultures and the end-points were based on cytopathic effect observed after incubation for twenty-seven days. The viruses isolated were identified by the serum neutralization test. Negative materials were tested in at least twelve cultures of HeLa cells, each inoculated with 0·1 ml. of undiluted material and observed for twenty-seven days. Blind passages of negative HeLa cell cultures were performed on several occasions and gave uniformly negative results.

Complement-fixing and neutralizing antibodies could not be demonstrated in any of the rabbit sera collected three days after inoculation; but in all animals kept beyond this period both these antibodies were detected at six days and usually reached maximum levels at 13–20 days after inoculation. The antibody titres reached at this time were maintained throughout the period of observation.

Inoculation of the spleen homogenates into HeLa cell cultures revealed the presence of adenovirus type 5 at a concentration of $10^{1\cdot 6}$ 50 per cent tissue-culture doses in the spleen suspension from the rabbit killed three days after inoculation. All the remaining spleen suspensions gave negative results when similarly tested. The same virus was, however, recovered from each of the spleen tissue cultures after varying periods of incubation. Fig. 1 shows the virus infectivity titres reached in successive fluids obtained from spleen cultures of the rabbit killed twenty days after inoculation. This result is representative of the series under study, but the time at which virus could first be detected in culture fluids was variable and tended to be prolonged with increasing intervals after the rabbits were inoculated. Some of the rabbit spleens under study were cultivated in plasma clot roller tubes or in cellular sheets obtained by trypsin treatment. The outgrowth observed in these cultures consisted mainly of fibroblast-like cells, and no signs of cytopathic effect could be observed in cultures shown by tests in HeLa cells to be supporting virus multiplication. It has, however, been observed that inoculation of large doses of adenoviruses into such cultures gives rise to a cytotoxic effect not associated with virus multiplication.

The present findings demonstrate the persistence of adenovirus type 5 in rabbit spleens for at least two months following inoculation. This has been the longest period tested so far. A few other experiments with the same virus type gave essentially identical results, but limited attempts to repeat this observation with adenovirus types 1, 2, 3 and 4 were not successful.

The similarity between our findings and those reported by Rowe *et al.*[1,5] with human adenoids and tonsils suggests that the present system may represent a useful experimental model for studies on latency and unmasking of adenoviruses. Attempts to elucidate the mechanism of unmasking are in progress and preliminary results are in agreement with the suggestion put forward by Rowe *et al.*[5] that the presence of neutralizing antibody in tissue suspensions may explain at least in part the failure to demonstrate virus in these materials.

We are indebted to Dr. C. H. Andrewes for his interest and constant encouragement in the course of this work.

Introduction of a Grapsoid Crab, *Brachynotus sexdentatus* (Risso), into British Waters

The grapsoid crab, *Brachynotus sexdentatus* (Risso) subsp. *gemmellaroi* (Rizza), has been found to be common in the Queen's Dock, Swansea. The crab is a Mediterranean form[1], which does not seem to have been recorded previously in Britain. Indeed it appears that this is the first record of *Brachynotus sexdentatus* north of the Mediterranean. Specimens have been compared with material in the British Museum (Natural History) and their identification has been kindly confirmed by Dr. Isabella Gordon.

Queen's Dock is artificially warmed by sea water which passes through a nearby electrical power station, and the crab lives together with *Carcinus maenas* Leach among stones which are encrusted with such organisms as *Balanus amphitrite* Darwin, *Hydroides norvegica* (Gunnerus) and *Mercierella enigmatica* Fauvel. Shipping using the Dock consists mainly of oil tankers, some of which load in the eastern Mediterranean, and it seems likely that the crab has been transported by these vessels.

Wolff[2] records several examples of the transportation of crabs by ships, and those introduced to north-western European waters are *Planes minutus* Leach, *Eriocheir sinensis* Milne-Edwards, *Pachygrapsus transversus* Gibbes, *Callinectes sapidus* Rathbun and *Rhithropanopeus harrisi* Gould. Of these, *Eriocheir sinensis* has become established in several estuaries on the Continent[3,4], and *Rhithropanopeus harrisi* became established in the Zuider Zee (at least since 1876)[5] and in the South Harbour at Copenhagen[2].

Examination of ships in dry dock suggests that hull fouling itself would be an unsuitable habitat for the transport of crabs, unless a vessel had been in harbour for a considerable length of time. *Planes minutus* may cling to fouling algae, but the species is often found among floating weed[4], and it may occasionally reach the west coasts of Britain from North America among floating weed or timber[6]. In addition, occasional records of the American blue crab, *Callinectes sapidus*, in European waters may be accounted for in this way, or it may be transported in the ballast tanks of ships[2]. *Eriocheir sinensis* was probably carried in ballast tanks[3] and *Rhithropanopeus harrisi* may have been carried in the same manner[2]. *Pachygrapsus transversus* was found among external hull-fouling on a wooden ship in the harbour at Copenhagen, but the vessel had previously been docked for some time at Bermuda[7].

Brachynotus sexdentatus normally hides in crevices between stones, and it may be transported by sheltering beneath the grids which cover the sea inlet valves to the oil-storage tanks of tankers. Normal fouling seems inadequate to provide a foothold for *Brachynotus*, and shipping enters the Dock fully loaded and not in ballast. The lowest temperature recorded in the Dock during the winter of 1956–57 was about 14° C. and salinity values never went below 30‰, so it appears that the crab could tolerate at least a summer voyage from the Mediterranean to British waters.

I am indebted to Mr. W. A. Morris, dock manager, for permission to carry out a faunistic survey of Swansea Docks and to Prof. E. W. Knight-Jones for much assistance. It is hoped to publish elsewhere descriptive notes on the specimens.

Production of Carbon in the Sea

THE oxygen equivalent of the daily production of carbon in the North Sea, reported by D. H. Cushing[1], ranges from 0·010 to 0·050 milligrams of oxygen per litre. These quantities, which could influence the saturation of a likely sea water to the extent of about 0·012–0·06 per cent, are much less than the 8–10 per cent supersaturation reported in different seas at the time of photosynthetic activity.

A plant growing in air can be enclosed for the study of photosynthesis without stimulating a bacterial flora which the enclosure of plants growing in a sea water always seems to do, with the risk of competition for a limited supply of nutrients. Under quiet sunny conditions, the inshore waters of the English Channel can become 50 per cent supersaturated with oxygen, as they did on several days in July 1956, with an oxygen production of some 1·7 mgm. per litre, equivalent to a round 650 mgm. of carbon per cubic metre on the scale used by Cushing. On April 13, 1957, at 8.45 hr., the sea was found to be 104 per cent saturated with oxygen. During the next seven hours, the oxygen content in the ambient sea rose by 1·79 mgm. per litre. Between 11.15 hr. and 13.20 hr., the oxygen rose by 0·94 mgm. per litre.

The carbon-14 technique for following the absorption of carbon dioxide is far more sensitive and elegant than the chemical estimation of oxygen, but it is suggested that some oxygen estimations should be made on the more active parts of the bulks of sea water from which the samples are taken for enclosure, in order to provide some certainty that the results are not only those of a laboratory exercise.

[1] Cushing, D. H., *Nature*, 179, 876 (1957).

THE measurement of oxygen production for a short period using black and clear bottles to separate respiration from photosynthesis[1] yields results in eutrophic waters similar to those using the carbon-14 technique, provided that the experiments do not last longer than 24 hr.[2]. My experiments lasted three hours, during which time bacterial effects will be small.

My results are similar to those of Steemann Nielsen off the mouth of the English Channel[3] and are of the order expected from the yearly production of about 80 gm. carbon/m.[2] from changes in phosphorus, nitrogen and carbon dioxide[4]. Dr. Oliver's observation of 10–20 gm. carbon/m.[2] in seven hours in inshore waters is of considerable interest.

FORTHCOMING EVENTS

Tuesday, September 24

WOMEN'S ENGINEERING SOCIETY, MANCHESTER BRANCH (at the Society of Chartered Accountants, 46 Fountain Street, Piccadilly, Manchester 2), at 6.45 p.m.—Miss Anne Shaw: "Training and Opportunities for Women in Engineering".

Tuesday, September 24—Thursday, September 26

SOCIETY OF CHEMICAL INDUSTRY (in the William Beveridge Hall, Senate House, University of London, W.C.1)—Conference on "Industrial Carbon and Graphite".

Wednesday, September 25—Thursday, September 26

IRON AND STEEL INSTITUTE, IRON AND STEEL ENGINEERS GROUP (at Church House, Westminster, London, S.W 1)—Meeting on "Air Pollution in the Iron and Steel Industry".

Thursday, September 26

PHYSICAL SOCIETY, ACOUSTICS GROUP (in the Physics Department, Imperial College, South Kensington, London, S.W.7), at 5.30 p.m —Dr. J. W. F. Bell: "Sound Propagation in Solids".

Friday, September 27—Saturday, September 28

INSTITUTE OF PHYSICS, ELECTRONICS GROUP (at the Brunel College of Technology, Acton, London, W.3).—Conference on "Transistors".

Saturday, September 28

ASSOCIATION OF CLINICAL BIOCHEMISTS (joint meeting with the ASSOCIATION OF CLINICAL PATHOLOGISTS, at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 9.30 a.m.—Scientific Meeting. 5 p.m.—Annual General Meeting.

BRITISH INTERPLANETARY SOCIETY (at Caxton Hall, Caxton Street, London, S.W.1), at 6 p.m.—Prof. S. F. Singer: "Geophysical Research with Artificial Earth Satellites".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

FORESTRY OFFICER (with a degree in forestry from a British university, and practical experience in forestry work) IN THE PLANNING DEPARTMENT, Durham County Council, for work on schemes for the planting of derelict pit heaps, tree preservation orders, felling licences, park layouts, etc.—County Planning Officer, 10 Church Street, Durham (September 26).

LECTURER IN STATISTICS—The Secretary, Birkbeck College, Malet Street, London, W.C.1 (September 27).

CIBA FELLOW (with an honours B.Sc. or equivalent, and preferably some knowledge of physiology) IN BIOCHEMISTRY in the Department of Surgery, to work as a member of a team investigating endocrinological problems related to surgery—The Secretary, Queen's University, Belfast (September 28).

LABORATORY TECHNICIAN for physics, chemistry and biology laboratories—The Secretary, Paddington Technical College, Saltram Crescent, London, W.9 (September 28).

LECTURERS (2) IN THE DEPARTMENT OF PATHOLOGY—The Secretary, The University, Edinburgh (September 28).

ASSISTANT LECTURER (with good qualifications and teaching experience in geography) IN EDUCATION—The Registrar, University College of North Staffordshire, Keele, Staffs (September 30).

LECTURER; and a RESEARCH ASSISTANT (Academic) IN THE INSTRUMENT TECHNOLOGY SECTION, Physics Department, R.C.S.—The Professor of Instrument Technology, Physics Department, Imperial College, London, S.W.7 (September 30).

LECTURER IN EXPERIMENTAL AERODYNAMICS—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks (September 30).

PROFESSOR OF APPLIED MATHEMATICS—The Registrar, University Office, 46 North Bailey, Durham (September 30).

RESEARCH ASSISTANT (with a first- or second-class honours degree in chemistry with an ancillary biological subject, or chemistry with physiology in the final year of the honours degree) IN BIOCHEMISTRY in the Department of Physiology and Pharmacology—The Clerk to the Governors, Chelsea Polytechnic, London, S.W.3 (September 30)

STAFF TUTOR (with good qualifications in any branch of the physical sciences) IN PHYSICAL SCIENCE—The Director of Extra-Mural Studies, The University, Edmund Street, Birmingham 3 (September 30).

LECTURER (Grade I or II) IN LOW TEMPERATURE PHYSICS—The Registrar, The University, Bristol (October 1).

LECTURER IN ELECTRICAL ENGINEERING; a SENIOR LECTURER (with industrial and/or research experience, and capable of initiating and supervising work of research assistants) to teach electronics and physics to B.Sc. general and special degree level; and a LECTURER to teach physics to B Sc general and special degree level—The Registrar, College of Technology, Birmingham (October 2).

ASSISTANT LECTURER IN APPLIED MATHEMATICS—The Registrar, The University, Sheffield (October 5).

STATISTICIAN (Scientific Officer) (with an honours degree in mathematics, either including statistics or with a postgraduate diploma in statistics, and preferably experience in applying statistics to biological problems) for the design and analysis of experiments—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (October 5).

LECTURER or ASSISTANT LECTURER IN PSYCHOLOGY—The Registrar, The University, Hull (October 7).

LECTURERS (2) IN GEOGRAPHY at the University of New England Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London W.C.1 (Australia, October 12).

MEDICAL ENTOMOLOGIST (with at least a second-class honours B.Sc degree with entomology or zoology as major subjects, or a higher academic qualification) with the Government of the Federation of Rhodesia and Nyasaland—The Secretary (R), Rhodesia House 429 Strand, London, W.C.2 (October 12).

ZOOLOGIST (with an honours degree, and preferably with some experience of research in marine biology) at the Scottish Marine Biological Association's Edinburgh Laboratory, to join a team studying plankton in relation to the herring—The Officer-in-Charge, Oceanographic Laboratory, 78 Craighall Road, Edinburgh 6 (October 15).

ANALYST (with a B Sc. degree, preferably with honours in organic chemistry or equivalent, and an interest in biochemistry and animal nutrition research) IN THE NUTRITION RESEARCH LABORATORY Department of Agriculture, Glenfield, New South Wales, Australia for duties which include the supervision and testing of analytical procedures in biological chemistry (Vitamin A blood ketone assays etc.) involving techniques such as paper chromatography and spectrophotometry—The Agent-General for New South Wales, 56 Strand London, W.C.2 (October 18).

PROFESSOR OF HORTICULTURE—The Registrar (Room 9 O.R.B.) The University, Reading (October 18).

LECTURER/SENIOR LECTURER IN VETERINARY PATHOLOGY AND BACTERIOLOGY at the University of Sydney, Australia—The Secretary Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, October 19).

NUFFIELD FELLOW IN EXTRACTION METALLURGY—Prof. F. D Richardson, Imperial College, London, S.W.7 (October 30).

KEEPER OF THE OTAGO MUSEUM AND LECTURER IN ANTHROPOLOGY at the University of Otago, Dunedin, New Zealand (joint appointment)—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1, (New Zealand October 31).

LECTURER IN FOREST MANAGEMENT at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia October 31).

LECTURER IN MATHEMATICS at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W C.1 (October 31)

LECTURER or SENIOR LECTURER IN BOTANY at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, October 31).

SENIOR LECTURER and a LECTURER IN THE DEPARTMENT OF PHYSICS, University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, November 1).

METALLURGIST, Basic grade (with A.I M. or exempting qualifications, and appropriate experience including process working of metals) to assist in the management of a team engaged in the production of components in radioactive metals and to take part in the development of process techniques—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berkshire, quoting Ref. B/1336/34.

PHYSICAL CHEMIST in the Pneumoconiosis Unit of the South African Institute for Medical Research, Johannesburg, to work on the physical chemistry of proteins and other large molecules encountered in silicosis and related lung diseases—The South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2.

QUALIFIED TECHNICIAN (male or female) IN THE PATHOLOGICAL LABORATORY—The Secretary, Wembley Hospital, Wembley Middlesex

REGIONAL TRIALS OFFICER, to work at the County Institute of Agriculture, Winmarleigh Hall, Lancs., and an ASSISTANT TRIALS OFFICER, to work at Leeds University Farm, Headley Hall, Yorks—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

RESEARCH ASSISTANT (with a science degree) IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY, to assist with research on the biological action of copper—The Physiology and Biochemistry Department, The University, Southampton.

SOLID STATE PHYSICIST or CHEMIST (preferably with radiation experience) at a National Laboratory, to assume responsibility for the direction of studies concerned with effects of nuclear radiation on semi-conductor materials—American Nuclear Science Corporation, 61 Broadway, New York 6, N.Y., U.S.A.

TECHNICAL ASSISTANTS (2) (women, with experience of hand computing and of programming for electronic computers) in the University of London Computation Unit which will be equipped with a Ferranti Mark II mercury computer—The Secretary to the Senate, University of London, Senate House, W.C 1.

LECTURES AND COURSES

WOOLWICH POLYTECHNIC

COURSES OF SPECIAL EVENING LECTURES IN HIGHER TECHNOLOGY

Commencing Autumn Term—Season 1957-58

(a) ADVANCED MATHEMATICS I

Twenty-eight lectures commencing Thursday, October 3, at 6 30-9 p m · By J. I. SONN, B.Sc (Eng.), A.M.I.E.E

(b) ADVANCED MATHEMATICS II

Twenty-eight lectures commencing Wednesday, October 2, at 6.30-9 p.m By G. C STALKER, M A (Edin), M A (Cantab.).

(c) NUMERICAL METHODS

Twenty lectures commencing Monday, September 30, at 6.30-9 p m. By H H. JOHNSON, M.Sc.

(d) ELECTRICAL METHODS IN ANALYTICAL CHEMISTRY

Eight lectures commencing Tuesday, October 22, at 7.15-8 30 p.m. By G F. REYNOLDS, M.Sc , F R.I.C

(e) PESTS OF FOODSTUFFS AND STORED PRODUCTS

Twelve lectures commencing Monday, October 7, at 6 30-8 p.m. By C. S. WOOD-BAKER, M.Sc., Ph D., F.Z.S , F.R E S.

(f) INSECT PESTS AND FUNGAL DISEASES IN HORTICULTURE AND MARKET GARDENING

Twenty-four lectures commencing Monday, October 7, at 6 30-8 p m By C. S. WOOD-BAKER, M Sc., Ph D., F.Z.S , F.R.E.S.

(g) APPLICATION OF PLASTICS IN ENGINEERING

Six lectures commencing Wednesday, November 6, at 7-9 p m. By Specialists from I.C.I.

(h) SOME RELAXATION TECHNIQUES IN ELECTRICAL ENGINEERING

Six lectures commencing Thursday, October 24, at 7-9 p m By G F. FREEMAN, M.Sc (Eng.), M I E.E., A.M I.Mech E.

(i) PLASTIC WELDING FOR PLUMBERS

Eight lectures commencing Friday, October 4, at 7-9.30 p.m. By—Lecturers to be appointed.

(j) PUNCHED CARDS IN OFFICE AND FACTORY

Eight lectures commencing Monday, October 7, at 7-9 30 p m By L R. CRAWLEY, M O M.A., M.S.I.E., A.M I.I.A , A.I.Prod.E.

(k) INDUSTRIAL RELATIONS TO-DAY

Eight lectures commencing Wednesday, October 9, at 7-9.30 p.m. By MARY S. COUSINS, M A., Dip. Social Studies, M.I.P.M

(l) RECENT CHANGES IN CONSTITUTIONAL LAW

Eight lectures commencing Thursday, October 10, at 7-9.30 p m. By—Lecturer to be appointed.

(m) ORGANIZATION AND METHOD IN THE MODERN OFFICE

Eight Lectures commencing Friday, October 11, at 7-9.30 p.m By H. W. S. MEAD, A.C.W.A.

(n) THE DESIGN AND FORM OF INDUSTRIAL PRODUCTS

Six lectures commencing Monday, November 4, at 7.30-9 30 p.m By INDUSTRIAL DESIGNERS OF NOTE.

(o) WINES

Six lectures commencing Thursday, October 3, at 7-9 p.m. By—Lecturer to be appointed.

FEES · Courses (a), (b) £2 5s.
Courses (c), (f) £2.
Courses (d), (e), (i), (j), (k), (l), (m) £1
Courses (g), (h), (n), (o) 10s.

ENROLMENT · By personal application from 9 a.m. to 8.30 p.m. or by postal application to the Secretary.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY

DEPARTMENT OF CHEMICAL ENGINEERING

Course of eight lectures on "Principles of Fire Prevention and Control" by Dr. J H. Burgoyne on Monday afternoons at 2.30 p m. Commencing October 21, 1957.

Further particulars from Deputy Registrar, City and Guilds College, Exhibition Road, S W.7.

UNIVERSITY COLLEGE LONDON (GOWER Street, W.C 1) Professor M. Heidelberger (Institute of Microbiology, Rutgers, U.S.A.) will give a Public Lecture entitled "The Chemistry of Proteins and Carbohydrates in Relation to Immunological Specificity" on Tuesday, October 1, at 5 p m. Admission free, without ticket. —H. A. L Gueterbock, Secretary

---

CHELSEA POLYTECHNIC

(COLLEGE OF ADVANCED TECHNOLOGY)

DEPARTMENT OF CHEMISTRY

SANDWICH COURSE IN CHEMISTRY

The Sandwich Course in preparation for the examinations leading to Graduateship of the Royal Institute of Chemistry commences in January, 1958. The course (works based) is of four years' duration and involves six-months' study at College each year. The normal requirements for admission to the course will be successes at A Level (G.C E), or comparable examinations, in chemistry, together with physics and/or mathematics, and three suitable ordinary level subjects.

Inquiries from industrial firms, research organizations, and government departments will be welcomed Particulars from the Secretary, Chelsea Polytechnic, Manresa Road, S.W 3

OFFICIAL APPOINTMENTS

SOUTH AFRICAN COUNCIL FOR SCIENTIFIC AND INDUSTRIAL RESEARCH

PNEUMOCONIOSIS RESEARCH UNIT AT THE SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH, JOHANNESBURG

VACANCY FOR PHYSICAL CHEMIST

A vacancy exists for a Physical Chemist to work on the physical chemistry of proteins and other large molecules encountered in silicosis and related lung diseases. Modern techniques, such as electrophoresis and ultracentrifugation, will be available. The person appointed could also take an interest in other physico-chemical aspects of pneumoconiosis, e g , relationships between the surface properties of silica and its biological activity and/or radioactive tracer studies. The post offers an opportunity for an enthusiastic scientist to make a substantial contribution in a little explored and important field as a member of an integrated team. The salary will be commensurate with ability and experience on the scale £1,080 to £1,620 per annum. Cost of living allowance is paid to married men at Public Service rates, at present £234 per annum. The Council will bear the cost of transfer of the appointee and his family from their place of residence to Johannesburg and will contribute to the cost of transfer of household effects.

Application forms may be obtained from the South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2.

GOVERNMENT OF IRAQ

MINISTRY OF AGRICULTURE

DEPARTMENT OF VETERINARY SERVICES

Applications are invited from Veterinary Surgeons holding the Diploma M R C.V S. or an equivalent degree in veterinary science of an approved university, and he should be well acquainted with English language for the following appointments:

1. Veterinary Parasitologist.
2. Expert in meat and meat inspection.
3. Expert in diseases of sheep.
4. Expert in the control of the contagious diseases of animals

Candidates must not be less than 30 years of age and not over 50 years. They must be well experienced in their subjects.

The appointments in the first instance will be on probation for one year, subject to renewals.

The salary to be from ID150 to ID250 per month plus the high cost of living allowance (the Iraqi dinar equals one English pound or its equivalent in other foreign currency)

Free passages provided in both directions for the appointee, his wife, and two children under 13 years of age. Selected candidates will be required to take up their appointments as soon as possible.

Application, with copies of references, to be made in the English language to the Director-General of Veterinary Services, Baghdad, Iraq.

Minister of Agriculture.

NATIONAL VEGETABLE RESEARCH Station requires Statistician (Scientific Officer) for design and analysis of experiments Scope for original work. Honours degree in mathematics, either including statistics or with postgraduate diploma in statistics. Experience in applying statistics to biological problems advantageous Salary for men £565 rising to £995 (£700 on confirmation) Salary for women lower but equal pay being introduced. Starting salary according to age, qualifications, and experience. F S.S.U superannuation.—Applications (four copies), giving three referees, to the Secretary, N.V R S., Wellesbourne, Warwick, by October 5, 1957.

IMPERIAL COLLEGE OF TROPICAL AGRICULTURE

TRINIDAD, B.W.I.

DEPARTMENT OF SUGAR CHEMISTR AND TECHNOLOGY

PHYSICAL CHEMIST

Applications are invited for the post of Ph cal Chemist in the British West Indies Sugar search Scheme in the Imperial College of Tr cal Agriculture, Trinidad. The work will be various aspects of sucrose crystallization and is considerable fundamental interest. Applica should possess a first- or second-class hono degree and should have some experience in related field such as chemical kinetics or crysta graphy. The appointment will be in the Sci tific Officer grade (basic salary in the range £ by £30 to £650, plus allowances in the range £ to £547), or Senior Scientific Officer's grade (ba salary in the range £750 by £30 to £950, p allowances in the range £522 to £592).

Further particulars can be obtained from Secretary, The Imperial College of Tropical A culture, 40 Norfolk Street, London, W.C 2, whom applications should be sent before Oc ber 31, 1957

IMPERIAL COLLEGE OF TROPICAL AGRICULTURE

TRINIDAD, B W.I.

DEPARTMENT OF SUGAR CHEMISTRY AND TECHNOLOGY

ANALYST

Applications are invited for the post of Anal to the British West Indies Sugar Research Sche in the Imperial College of Tropical Agricultu Trinidad. The work will mainly consist of vising new analytical techniques over a wide fie Applicants should possess a first- or second-cl honours degree and suitable analytical experien The appointment will be made in the Scient Officer grade (basic salary in the range £525 £30 to £650, plus allowances in the range £441 £547), or Senior Scientific Officer grade (ba salary in the range £750 by £30 to £950, pl allowances in the range £522 to £592).

Further particulars can be obtained from t Secretary, The Imperial College of Tropical Ag culture, 40 Norfolk Street, London, W C.2, whom applications should be sent before Oct ber 31, 1957.

METEOROLOGICAL OFFICE, SCIENTIF Officers The Civil Service Commissioners invi applications for permanent posts. The duties i clude research in atmospheric physics, coveri the study of cloud structure, synoptic and dynam cal meteorology, large- and small-scale diffusi and turbulence, climatology, and development instruments. There is a limited number of pos for forecasting work at the more importa centres. Successful candidates will be given course in meteorology before being assigned to research or forecasting establishment for furth training and experience. In some instances cand dates with National Service obligations can commissioned in the R A F. for forecasting duti at R.A.F. stations. Further information may obtained from the Director, Meteorological Offi (M.O. 10), Air Ministry, Kingsway, Londo W.C.2. Candidates must be between 21 and 2 during 1957. They must have a first- or secon class honours degree, preferably in physics mathematics, or an equivalent qualificatio Salaries (London rates) £635 to £1,110. Women' pay above £635 slightly lower but being raise to reach equality with men's in 1961. Somewh lower rates in provinces. Opportunities for pro motion to Senior Scientific Officer (£1,190 t £1,410), and higher posts.—Particulars from Civ Service Commission, Scientific Branch, 30 Ol Burlington Street, London, W 1, quoting No S.52/57 (Mét). Interview boards will sit at in tervals as required. Early application is advised

---

APPLICATIONS ARE INVITED FOR post of Physicist in the Colonial Insecticide Re search Unit stationed at first at Porton nea Salisbury, Wilts. This Unit may be transferre to London shortly. Applicants must have a goo honours degree in physics or an equivalent quali fication The successful candidate will be re quired to conduct research on physical problem relating to the application of insecticides. Th appointment is for two years in the first instanc with a likelihood of extension. F.S.S.U. mem bership provided. Salary according to age, ex perience, or special qualifications, in the Scienti Officer scale £635 to £1,110 (men) or the Senio Scientific Officer scale £1,190 to £1,410 (men) with appropriate deductions for provincial differ entations.—Application forms available fro Colonial Office, London, S.W.1; quoting referenc RES 58/59/01.

Do you need

one copy—or several?

Every organisation has its own particular document-copying requirements, so you alone can decide which copying method would be most suitable for your purposes.

For example, is time a very important factor? Would you require one copy of a document, or several? Would originals be single-sided or double-sided? Who would use the equipment? Would copies have to be despatched immediately? These and other factors must influence your choice.

So before you start buying, get in touch with Kodak, who have an immense amount of document-copying experience behind them. They will provide you with a great deal of information that should help you to select the most suitable method for your particular needs.

E·I·L

The VIBRON

is a new electronic component, which replaces the electrometer valve in the measurement of very small currents.

The VIBRON is a vibrating condenser unit which, in a suitable circuit, can measure currents as small as 10^{-16} ampere, or resistances as high as 10^{15} ohms, to an accuracy of ±2% and with a zero stability of ±100 microvolts in twenty-four hours. It can be supplied as a unit for building into instruments of your own design, or, alternatively, VIBRON instruments of several types are available from E.I.L.: the Model 33B Electrometer shown here is an example.

Manufactured under British Patent No. 550610 and Patent Application No. 35637/54.

EDUCATION FOR TECHNOLOGISTS

THE year 1485 is usually regarded as the one when the spirit of learning was re-born after long years of darkness; and although the Renaissance is no longer regarded as "a sudden explosion of dawn at the end of a long night of Stygian darkness", it may well be that, to future historians, the year 1957 may come to be regarded as the one marking the birth of a revolution in technical education in Britain. Conception began with the White Paper on Technical Education; gestation has been accompanied by the creation of the Council for Technological Awards. To mark the birth, the new academic year will see most of the colleges of advanced technology beginning to function in the roles for which they were intended. All this has been accompanied by tremendous stirrings in the technological departments of the universities, where, despite magnificent progress since the War, present output of technologists is acknowledged to be pitifully small for the needs of the nation.

These are the outward signs by which the future historian will trace the onset of the revolution. The significant feature of 1957, however, is that, really for the first time, those in authority in government and industry have realized that knowledge of the humanities is no longer enough; the future administrator will be required to make judgments based on substantial knowledge of complex technological processes. In many ways, therefore, 1957 may be regarded not only as a beginning but as the end of an era which began in 1485.

It is an era which has already lasted too long for the good of Britain. In 1485 knowledge of Latin and, to a lesser extent, Greek was essential if men were to make progress in the Church, in education, in government or the administration of large estates. In 1957 the large majority of the country's administrators in all fields of endeavour are men with little or no knowledge of science and technology; many of them, until quite recently, have been proud of their ignorance and condescending to those who, far too long, have been dubbed as narrow specialists. Their own deficiencies in science lay in an educational system which they were mainly responsible for contriving and where knowledge of science was not considered necessary in the make-up of a gentleman. There is little doubt that technological progress in Great Britain over the past fifty years would have been much more rapid if, to quote a leading industrialist, a few senior members of the Ministry of Education had been men with substantial acquaintance with some branches of science.

Mistakes of the past should guide those responsible for the educational system required in the new era of technology. Experience has shown that technological education alone is not enough to make the successful legislator, administrator, governor or teacher; specialisms need supplementing by studies based on the humanities. This is a matter with which Sir Eric Ashby recently concerned himself in an address to the Institute of Metals (see p. 624 of this issue); it confirms his right to be accepted as one of Britain's most thoughtful educationists.

The gist of Sir Eric's address is that, because our educationists have made two unfortunate assumptions, the present system for producing technologists takes no real account of the humanities. These inaccurate assumptions are that technologists receive a balanced schooling with a thorough grounding in the humanities, and, equally dangerous, that the technologist is expected to become and remain an expert destined to serve the managing director but never to become one himself. The future of the West will be greatly influenced by the way in which the education of the technologist can be liberalized and the rapidity with which such men gain seats in the board room.

The challenge to Britain is greater than to other industrial countries of the West. In his address, Sir Eric refers to the liberal influence in technological courses provided at the Federal College of Technology, Zurich, the Technical University of Delft and the University of Technology in New South Wales. Despite her concern for turning out the greatest number of technologists, even the Soviet Union has technological institutions which devote some time to the humanities and the social sciences. The odd lectures on music, the fine arts and the like in British universities stand out in sharp contrast to the extensive range of general educational courses provided in the American universities. In a recent report of the American Society for Engineering Education, for example, a committee largely made up of men drawn from academic circles recommends that the humanities and social sciences be given "a minimum of approximately 20 per cent of the student's educational time". The Engineers' Council for Professional Development, which draws its members from all the professional engineering institutions, will not recognize curricula unless "the equivalent of one-half year to one full year of the curriculum shall represent the minimum content in the area of humanistic-social studies. Of this content, at least one-half year should be selected from the fields of history, economics, government, literature, sociology, philosophy, psychology or fine arts". That these recommendations represent not too pious hopes was illustrated by a survey recently carried out by the U.S. Office of Education which showed that, on average, about 16 per cent of the time at engineering schools is given over to humanistic-social studies.

The way in which these courses are arranged in the United States varies from college to college. In some, the liberal element precedes the technological course; in others humanistic-social studies are intermingled with professional. What is taught also varies from institution to institution. The California

Institute of Technology, for example, stresses the humanities; the Carnegie Institute of Technology is more concerned with the social sciences. At the Massachusetts Institute of Technology the liberalizing influence stems mainly from study of one particular selected field; this ensures that some at least of the humanities are studied in depth. The Massachusetts Institute of Technology also has four-year curricula leading to the degree of B.Sc. in humanities and science, or B.Sc. in humanities and engineering.

Despite the occasional and inevitable protests from American professors about crowded technological curricula, nearly all those responsible for training technologists are convinced that the advantages gained by including humanistic-social studies in the curricula far outweigh the disadvantages. Such powerful testimony adds weight to Sir Eric Ashby's plea for including serious studies in the humanities in the time-tables of all degree courses. The content of the courses and the way they are spread over the time-table should be left to individual universities. For some, intermingling may appear to give the desirable pattern. Others may follow Sir Richard Livingstone's advice that liberal studies are more appreciated when students have had some experience of life; they will prefer to let studies of the humanities follow concentrated professional courses[*]. What matters most is that some at least of our universities should offer courses of study in the humanities to technological students and that these studies should be reinforced by examination. Those first in the field would find their products greatly sought after by industry.

Sir Eric's suggestion for including liberal studies as an integral part of university technological courses is likely to be resisted by those who believe that broad general education should be provided in the schools and that specialization should be left to the universities. Desirable as this may be, experience in other countries has shown that it is not enough. Teaching students to make balanced value-judgments and to express ideas clearly, to appreciate distinctions between right and wrong, good and evil, to examine the concepts of freedom and justice, can be better done, as Sir Richard Livingstone has shown, with students of mature years.

The provision of courses in the humanities for technological students would have the advantage of stimulating students to read. Too many of them, brought up on a strict diet of lecture notes which are sufficient for examination purposes, leave the universities with good degrees but little or no desire to continue their reading. If conducted on tutorial lines with set reading as a prominent feature of the course, many technological students would find deeper interests which should encourage them to make inquiries in ever-extending horizons. Already many graduates in technology are seeking to widen their experience through extra-mural classes in liberal subjects. This number would increase considerably if compulsory courses in the humanities were included as part of university technological courses.

Efforts to liberalize curricula in technical colleges[*], proposals to inaugurate a general course in arts and science at the University of Cambridge, the suggestion for a degree course in Science Greats[†], as well as the arguments which Sir Eric Ashby has put forward for courses in the humanities, all show that, in the educational system which is to serve the technological revolution, men shall be produced who will be equally capable of dealing with principles as with processes, with people as with production. The aim of the educational system should be to produce men like Alexander Nowell, the famous sixteenth-century headmaster of Westminster, who, besides his zeal in promoting the teaching of pure Latin, was the author of the Catechism and the inventor of bottled beer. What is now needed are men who can invent processes for producing better 'beer' more effectively and more economically; they should also be men who will consider the effects of their invention on the world at large.

COMMEMORATION OF PAUL EHRLICH'S GENIUS

The Collected Papers of Paul Ehrlich

In four volumes including a Complete Bibliography. Compiled and edited by Dr. F. Himmelweit. With the assistance of Martha Marquardt. Under the editorial direction of Sir Henry Dale. Vol. 1: Histology, Biochemistry and Pathology. Pp. viii + 653 + 6 plates. (London and New York: Pergamon Press, Ltd., 1956.) £12. (£28 or 85 dollars the set of four volumes.)

FOR those who have at heart the advancement of science, especially as bearing on medicine, the first and strongest feeling must be gratitude that publication of "The Collected Papers of Paul Ehrlich" now makes these readily available to all. For the motivation of this tribute we are indebted to Sir Henry Dale, and for the greater part of the burden involved in the execution of the project Dr. F. Himmelweit is to be thanked. Without the devoted loyalty to Ehrlich's memory of the late Miss M. Marquardt, his secretary for many years and until his death, the completion of the collection would have presented extreme difficulty. She preserved copies of his publications and unpublished manuscripts in circumstances of severe trial; and those documents along with her personal knowledge were of the greatest value to the editors. Some works, originally issued separately, were out of print, others were lodged in libraries and never printed, while the rest were scattered through many journals in different fields and the reports of societies and conferences. Thus, even with the help of the bibliography prepared by his co-worker, the late Prof. Hans Sachs, for the Paul Ehrlich (sixtieth birthday) *Festschrift* of 1914, much searching would have been needed to unearth some works. The Wellcome Trust, too, played a valuable part in facilitating publication by providing a guarantee against financial loss. These things are told in an introduction by Sir Henry Dale.

The collected works are arranged according to a list of subjects which corresponds, more or less, with the order of their issue. Every article has been reproduced in the language in which it was originally published and, of course, that is German in all but a few. According to the introduction, however, the publishers considered such a preponderance would have a very adverse influence on sales and hence on the general availability and use of the work. Therefore, as an attraction, English translations of certain important papers have been added. It may be doubted, however, if those who mean to assess critically the value and influence of Ehrlich's views can afford to neglect the original German. In any event, the cost of the volumes would seem to discourage their acquisition except by institutional libraries. The account of the pains which have been taken to reproduce the text faithfully, and even to revise it (in the case of "Histology of the Blood", etc., where an English translation, published earlier, has been adopted), should disarm criticism.

Volume 1 contains fifty-five works under the headings "Practice and Theory of Staining in Histology" (this includes "Beiträge zur Theorie und Praxis der histologischen Farbung", presented in 1878 to the University of Leipzig as an inaugural dissertation and hitherto unpublished, with an English translation); "Cytology of the Blood in Health and Disease" (comprising works which form the basis of modern morphological hæmatology); "Staining of Bacteria and its Application to Diagnosis" (among which is the discovery of the acid-fast property of the tubercle bacillus); "The Requirement of the Organism for Oxygen and Allied Biochemical Studies" ("Das Sauerstoff-Bedürfniss des Organismus" is here with its statements foreshadowing the side-chain theory and much else that runs through Ehrlich's later work, and an English translation is appended; curiously, an article on the action of acid chlorides on nitrosodimethylaniline and the one describing the use of neutral red as a 'vital stain' have been placed in this section); "Pharmacology, Therapeutics and Toxicology"; "The Diazobenzenesulphonic Acid and Dimethylaminobenzaldehyde Reactions". Despite reasons given for the arrangement adopted, Volume 1 suggests strongly that the least objectionable sequence would have been according to dates of publication (or of completion where a paper was not published). A classified table of contents would then have been a valuable addition, showing the works grouped under subjects somewhat as in the scheme used.

Part of the introduction consists of an appreciation of Ehrlich's work and an assessment of its importance. A translation of a letter from Ehrlich to his friend and co-worker, C. A. Herter, which is included, lets one glimpse his own feelings about this (the absence of the original German is regrettable). This introduction and a notice in *Nature* by the writer (175, 570, 616; 1955) seem to be almost the only attempts in English to give the general scientific reader briefly an idea of the versatility of Ehrlich's accomplishments and the seminal quality of his work, which even now are not as widely known as they deserve. Sir Henry Dale mentions in passing that "there are those still living who believe that they remember having seen him . . . testing a sample of a dye for its purity, by pouring a solution of it down a suspended sheet of blotting paper and looking for the appearance of accessory adsorption bands! Paper-chromatography in embryo, it would seem". Others may know in how far this was an original procedure, but it may be worth while placing on record that some of us have never forgotten being present when he did so. It is impossible now for a single individual to relate thoroughly the value of the whole mass of contributions to present-day scientific knowledge and theory. Therefore it is hoped that when at last the collected works are available, specialists in each department represented will utilize them to provide a perspective of his achievements. To Sir Henry Dale it "appears proper" to claim for the revolutionary effect of Ehrlich's researches on what is termed chemotherapy that "it is comparable, at least, in its importance, to that which had been produced . . . by the researches of Joseph Lister". Surely the transcendent services of both men have placed them among the immortals.

C. H. Browning

MANAGEMENT ORGANIZATION

Organization

The Framework of Management. By E. F. L. Brech. Pp. xiv+424. (London and New York: Longmans, Green and Co., Ltd., 1957.) 45s. net.

MR. E. F. L. BRECH, who is a senior consultant with Urwick, Orr and Partners, has written an admirably lucid and comprehensive book on organization. This comprehensiveness means that his book could serve as a useful work of reference, but that, although any one passage is clearly written and his arguments are easy to follow, the whole tends to be indigestible. This probably cannot be helped, but it is a pity since the reader who lacks the necessary perseverance will miss many illuminating discussions which are based on Mr. Brech's wide experience of organization.

Mr. Brech maintains that recurrent experience has shown that the problem of divergence of authority and responsibility will disappear when responsibilities are correctly defined. The value of clearly defining management responsibilities and writing them down in detailed schedules is the main thesis of the book. This thesis is argued most persuasively and is illustrated by thirty sample schedules, although the detail of these schedules may make some readers quail.

The purpose of an organization structure is described as delegation of responsibility, hence in any organization there must be some decentralization. The effectiveness of decentralization depends upon three factors: the soundness of structure; the clarity, stability and continuity of direction from the top; and the competence, reliability and outlook of the subordinate executives and the specialist personnel. The factors selected show that Mr. Brech is very conscious of the human influences, as he says in conclusion: "From the structure the dynamism of motivation is, by definition, missing, but that does not detract from the importance of structure or the significance of its contribution to effective action".

Those who hope that Mr. Brech will offer a typical organization which they can copy will be disappointed, for all organizations must, he maintains, be tailor-made. There is probably no absolute right or wrong in organization pattern, but there are, he suggests, certain principles which should be used as a guide. Apart from his main thesis of clear definition of responsibilities, there is at least one other principle which he recommends which is certain to arouse considerable controversy, namely, that there should be only one chief executive.

This book has already been described as comprehensive, so the reader will expect and will find valuable discussions on such topics as the role of the specialist, the responsibility of top management, centralization versus decentralization, the effective use of committees and the role of organization charts. The latter is accompanied by a special warning against exaggerating what can be accomplished by them. There are specially illuminating discussions on the difficulties of executive directors, which Mr. Brech attributes primarily to a failure to distinguish between their dual roles; the harmfulness of deputy appointments which are used in some of the nationalized industries; and the factors which affect the span of control. Among the latter Mr. Brech includes the 'emotional' aspect of attention, that is the extent to which an individual can deal with interruptions as well as more obvious factors such as geographical distribution and the nature and diversity of responsibilities.

There are three interesting appendixes on the history of thought on organization, on the Fleck and Herbert Reports and on organization for command in the Army.

A board of directors which wishes to assess the effectiveness of its management might start from the list of factors given on p. 278 of Mr. Brech's book. These do not, of course, provide the answers, but periodic heart searchings on each of these points together with research, where necessary, would help to improve the efficiency of management by ensuring that the board was considering all relevant factors.

Rosemary Stewart

MICROSCOPY IN REVERSE

Microphotography

Photography at Extreme Resolution. By Dr. G. W. W. Stevens. Pp. xvi+326. (London: Chapman and Hall, Ltd., 1957.) 50*s*. net.

MICROPHOTOGRAPHY, which Dr. G. W. W. Stevens very properly distinguishes from photomicrography, can be defined as the copying of objects on an exceedingly small scale. The process is almost as old as photography itself, and a fine example, nearly a century old, by J. B. Dancer of Manchester, is reproduced in this book. Such a technique offers a challenge to the perfectionist, and enthusiasts express their results in terms of 'Bibles per square inch'. Some of the practical applications are fairly obvious; Nazi spies transmitted copies of secret documents in the full-stops of newspapers and telegrams, and the value of microphotographic books in space travel can be foreseen. On a more everyday plane the importance of storing information in a small volume needs no emphasis at a time when the number of scientific journals alone is increasing so rapidly that the storage space of many libraries is likely to become inadequate within the next generation.

Quite apart from its immediate practical value, microphotography is of great intrinsic interest, in that it brings together a large number of different techniques and disciplines. There is great scope for the development of new types of grainless photographic emulsions, and Dr. Stevens gives an account of these and of some of the special problems encountered in their use, which will certainly fascinate anyone interested in photography. The long sections devoted to optical techniques are of great interest to microscopists, and will help them to think about their problems from a new point of view. The beautifully illustrated chapter on anomalous image formation and spurious resolution will provide theoretical optical physicists with food for thought. The last hundred pages or so deal with practical applications. These range from the large subject of graticule manufacture through document copying to such diverse research methods as resolution testing, the study of fine mechanical movements and autoradiography.

This is a pioneer effort, and the author has not been able to make use of other text-books on the subject. It would be surprising if such a book were free from errors or if all sections were easy to read. Such things are of little importance and can be attended to in future editions. The really important fact is that this book should have been written at all, for it contains a mass of information which has hitherto been available only to specialists. Adequate references are provided after each chapter, and, as is to be expected, the numerous plates are of very high quality and unusually informative.

R. Barer

MAGNETIC AMPLIFIERS

Transductors and Magnetic Amplifiers

By Dr. A. G. Milnes. Pp. xiv+286+16 plates. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1957.) 63*s*. net.

THE magnetic amplifier is essentially a non-linear element and does not lend itself to a general solution. The extensive literature on this subject tends to treat particular aspects of it rather than give an overall generalized picture. This book gives a very complete survey, and attempts to bring the different aspects together and place them on a common foundation. The author is well known for his analytical treatments of the series and self-saturated magnetic amplifiers. These theories have been integrated into the book and give the specialist a valuable insight into their operation.

The introductory chapter describes the basic operation of the transductor, flavoured with a little of the analytical theory which is fully developed in the later chapters. The effect of core material and rectifier performance is discussed in detail, and typical figures for a range of 400 c./s. magnetic amplifiers with selenium rectifiers are given. Unfortunately the figures are rather out of date, as much better results are now obtained with silicon and germanium diode rectifiers.

Detailed analyses are given of the series-connected transductor with various degrees of positive feedback and the self-saturated magnetic amplifier. The *B–H* loop is approximated to three straight lines, having a finite slope in the unsaturated condition, and zero slope in the saturated conditions. Although this gives good agreement for current sensitivities achieved in practice, the omission of a hysteresis term from the approximation does not allow the absolute position of the input–output current characteristic to be estimated and gives, for square-loop materials, theoretical current waveforms which differ widely from those observed in practice.

The specialist will find the discussion on push–pull circuit operation, three-phase magnetic amplifiers and the effect of inductive and capacitive loads on general magnetic amplifier performance most informative and enlightening. The chapter devoted to magnetic amplifiers with a.c. control is too limited in scope to be of much value to the design engineer. The reader will find the design criteria for maximum power gain, which is of prime importance in this type of operation, overlooked. There is a similar lack of clear-cut design statements in the chapter on voltage reset and transistor magnetic amplifiers. However, the research worker will find these chapters stimulating for future development work.

The information given on magnetic amplifier applications and associated magnetic core devices enables the reader to get a very good appreciation of the practical state of the art. The four-limbed core magnetic amplifier, the magnetic modulator, ferro-resonant devices, magnetic counting and storage are a few of the topics discussed.

The mathematical treatments are of undergraduate level and have been kept to a minimum. The discussions are well supported with self-explanatory diagrams. The full-plate photographs give completeness to the descriptive details on magnetic amplifier construction and practice.

The diverseness of the information contained in this book cannot but broaden the reader's outlook in this field. Particular aspects of the subject can easily be followed up from the excellent appended bibliography. The theoretical treatments are sound, and give the student and specialist a valuable insight into magnetic amplifier operation. Engineers will find much useful design information. Although practical experience plays an important part in this matter, it is felt that the fundamental issues at stake could be more clearly stated, especially in the case of high-speed magnetic amplifier design.

D. F. WALKER

POPULARIZING THE INTERNATIONAL GEOPHYSICAL YEAR

Once round the Sun

The Story of the International Geophysical Year, 1957–58. By Dr. Ronald Fraser. Pp. 160+19 plates. (London: Hodder and Stoughton, Ltd., 1957.) 16s. net.

IN recent months members of national committees for the International Geophysical Year have been increasingly embarrassed by requests for information—from the Press, radio and television—about the organization and aims of this great scientific enterprise. These demands have been a challenge, not always easy to meet; for geophysics includes many interrelated sciences and the programme of the International Geophysical Year is necessarily directed towards the boundaries of existing knowledge.

In this little volume we have the first popular and comprehensive account designed to meet the needs of a wide public. The author, Dr. Ronald Fraser, is well equipped for his task, being the administrative secretary of the International Council of Scientific Unions—the parent body which sponsored and set in motion the project of the International Geophysical Year some six years ago.

The book is divided into two parts. In the first the reader is skilfully introduced to some of the real problems which now confront the geophysicist. These discussions range over such topics as fossil magnetism, continental drift, climate and weather, the ionosphere and solar-terrestrial relations. The second part deals with the planning of the Geophysical Year from its inception. There is a fascinating chapter on Antarctica. This is illustrated with fine photographs and describes the setting up of the various bases by the nine different countries which are now operating in that inhospitable and largely unknown continent. Another chapter tells of the plans for the rocket and satellite programmes. The language is everywhere simple and concise; the style humorous and imaginative.

Here and there one comes across statements which require correction or modification. Thus we read (p. 88)—"solar flares, no matter how intense, that occur far out towards the periphery of the sun's disc, are *not* followed by magnetic storms in the earth's upper atmosphere; whereas there is a practically one-to-one coincidence between the number of flares near the centre of the sun's disc and that of great magnetic storms on earth". It has been shown by H. W. Newton in his celebrated papers on this subject that the "*one-to-one coincidence*" between flares and subsequent storms applies only to intense (Class 3+ and 3) flares; the relationship breaks down for the much more numerous flares of Classes 2 and 1. Again, it is the probability that a great storm will follow an intense flare which decreases as the flare is located nearer to the Sun's limb. There have, indeed, been a few examples of great storms following upon flares near the limb (for example, that of January 25, 1938), but this sequence is rare. We infer that the emission of the magnetic storm particles from a flare takes place within a cone-shaped beam, the semi-vertical angle of which is normally less than 45°, but may be as great as 90°.

Commenting on the present wastage of the northern glaciers (p. 119), the author mentions that if the ice sheet covering Antarctica were to melt the average sea-level would rise by nearly 200 feet. Then follows the statement: "This might conceivably happen in say 10,000 years, but an initial rise in the average sea-level of, say, 30 feet in 10 years is not impossible". The reader may find so great a difference between what is "conceivable" and "not impossible" both puzzling and alarming.

On p. 137, and again in the illustration opposite p. 140, the auroral all-sky camera is said to employ a "convex lens". This should read "convex mirror". On p. 118 the author refers to two cosmic galaxies which "collided tens of millions of light-years ago". The light-year, of course, is a unit of distance, not of time.

However, these are trivial blemishes in what is at once a most entertaining and illuminating account of a great scientific venture. We can confidently recommend Dr. Fraser's "Story of the International Geophysical Year" as an admirable piece of popular exposition.

M. A. ELLISON

HUMANITIES FOR THE TECHNOLOGIST*

By SIR ERIC ASHBY
Vice-chancellor of The Queen's University, Belfast

MODERN technology is confronting us with an exceedingly perplexing biological problem. It lies in the field of human ecology. It is the problem of how men and communities can adapt themselves to an environment which is changing with unprecedented speed. Napoleon, who died only 136 years ago, was not able to cross the Alps any faster than Hannibal crossed them. To-day you can have breakfast in London and lunch in Rome. Gladstone, who died less than two generations ago, was not able to reach more people with his voice than Demosthenes reached with his. To-day a Prime Minister's voice can be heard in the homes of millions. The rate of change in the past hundred years is of a different order from that in previous centuries; and the changes are not merely advances in technology: they are drastic transformations in the environment of man.

In contrast to this, man remains very much as he was when history began. He learns no more efficiently than a pupil in Plato's Academy learnt. He thinks no more deeply than Plato thought. His chromosomes are conservative and resistant to change. He responds to new environments not by innovations in his heredity but by the marvellous adaptability of his ancient genetic heritage. This adaptability would be impossible if the only channel of inheritance from one generation to the next were through the sperm and the egg. In man—and in man alone—there is a second channel of inheritance. The accumulated knowledge and traditions of society are inherited not through the chromosomes but through education. Over this channel of inheritance we have some influence and we can assume some responsibility.

This gigantic problem—the adaptation of society to a rapidly changing environment—confronts teachers of all kinds at every level of education. One aspect of it—the higher education of technologists—is the concern of universities, colleges of technology and professional institutes, and it is specially important because technologists are now becoming the pacemakers for social change; communities which formerly developed on the initiative of princes, or bishops, or financiers, or soldiers, now develop on the initiative of technologists. It is no exaggeration to say that the quality of education to be given to technologists may deeply influence the future of the West.

It is first of all necessary to recollect how technological education arose in Britain. The first Industrial Revolution was accomplished without scientists or technologists. Our industrial strength lay in our amateurs and our self-made men: the 'cultivator of science' (as he was called), the craftsman-inventor, the mill-owner, the ironmaster. It was no accident that the Crystal Palace, that radiant symbol of the supremacy of British technology, was designed by an amateur. In 1851 most people in authority saw no danger in the fact that Britain had no State system of primary education (a third of the population was still unable to read or write); or in the fact that there was scarcely any science teaching in secondary schools ("it is plainly out of the question", said Moberly of Winchester, "that we should teach chemistry"); or in the fact that there were no opportunities for the study of higher technology except a little in London and in Scotland. It did not seem worth while to spend money on popular education, for industry was flourishing and man-power was cheap; nor did there seem to be any reason why the well-to-do classes (who were concerned with administration and management and not with mere technical details) should depart from their traditional education in the classics.

Fortunately, there were men of foresight who were unhappy about this situation. The Royal Commission on the University of Oxford, for example, tried to encourage Oxford to pay attention to the physical sciences by saying that unless "the clergy and gentry . . . are encouraged to keep pace with the progress of Society at large . . . they may find themselves placed below persons in many respects inferior and an opposition may arise between Physical Science and other branches of knowledge"[1].

Such admonitions as these made very little impression on the managers and mill-owners and ironmasters of Britain. So, when the Society of Arts and the new government Department of Science and Art did set up schemes to encourage scientific education, these schemes were almost exclusively for the benefit of artisans and the "labouring poor". Clearly admonitions were not enough; a much more powerful impact was needed to overcome public inertia to technological education.

That impact was provided by the International Exhibition held in Paris in 1867. Britain had won awards in nearly every class in the 1851 Exhibition, but in the 1867 Exhibition she had to be content with a bare dozen awards. No longer was there the reassurance of easy industrial supremacy. Instead, there was alarming evidence that Britain had made little progress in the peaceful arts of industry since 1851 and that Continental countries had now become serious competitors.

What had happened in the interval between the two Exhibitions to bring about this change? There were many causes at work, but the chief cause undoubtedly arose from Britain's monopoly of much of the 'know-how' she had acquired during the Industrial Revolution. Up to 1825 it was a penal offence to enlist English artisans for employment abroad. Well on into Queen Victoria's reign, the export of spinning machinery to foreign countries was prohibited. When Continental countries began to build railways and mills and factories, they found it extremely difficult to obtain access to British techniques and practices. They had to make up for half a century of lost time. Their response was to produce a new species of professional man: the manager-technologist. To this end they established polytechnics with the specific purpose of training not the rank and file of workers, but engineers, designers, chemists and potential managers for industry. In Zurich, in Dresden, in Delft, even in the United States, there arose mid-century technological institutes which had no parallel in Britain. Their function is well summarized by the words used to describe the Massachusetts Institute of Technology (founded in 1864) as a place [1]"intended for those who seek administrative positions in business . . . where a systematic study of political and social relations and familiarity with scientific methods and processes are alike essential".

---

* Substance of the forty-seventh Annual May Lecture of the Institute of Metals, delivered at the Royal Institution on April 29, and published under the title "Technological Humanism" in the *Journal of the Institute of Metals*, 85, 461 (1957).

The prime purpose of this widespread system of technological education abroad was not humanitarian: it was to enable Continental countries to catch up with, and to overtake, British industry. Accordingly, in the polytechnics emphasis was laid on a combination of science, technology and general knowledge, suitable for men who would direct technical policy. Already by 1867 this experiment had begun to yield results. The results were obvious to Britain, and it was this challenge from the Continent, rather than a demand from industry at home, which drove Britain finally to set her educational house in order.

England could not meet the challenge from the Continent by building polytechnics, for she had no adequate foundation of schooling on which to build. So, even after the need for technical and technological education had been realized, the response was slow and uncertain. In 1870 the Government introduced compulsory primary education. But Parliament was still unwilling to support trade schools and technical schools; it was the Livery Companies which first undertook to assume this responsibility. In 1867 they set up the City and Guilds Institute, which fathered not only the first genuine technical college (at Finsbury) but also (at South Kensington) the first genuine institute for higher technology. Not until 1889 did public authorities take over elementary technical education, and even then education in higher technology was not made a public responsibility; most of it was left to the universities and university colleges.

Here is one clue to an understanding of the present curricula in higher technology in Britain. The spur to technological education in universities was not in the first instance a demand from industry for scientifically trained managers; it was the determination of a few far-sighted men to create a supply in anticipation of a demand. Accordingly, the pioneers of technological education in universities found themselves having to justify their subjects on academic and not on utilitarian grounds. They could not prove to their academic colleagues that higher technology was useful, and so they had to make it appear respectable. Accordingly they felt obliged to follow the fashions set by more venerable faculties. Therefore, when, under the influence of German scholarship, specialization became fashionable, technology followed the fashion. Part of the price paid for following the fashion was a narrowing of the curriculum in every discipline—not only in technology. No longer was it necessary for a man taking the classical tripos at Cambridge to pass first a tripos in mathematics and mechanics. No longer did the London B.A. require some knowledge of both the humanities and the sciences. Higher technological education abroad was from the beginning intended to produce not only experts but also managers and leaders in industry. In the British economy of the 1860's and 1870's there was no shortage of men for the board-room: the shortage was in the design office, the laboratory, and the plant; therefore, the pattern of higher technological education set in Britain at that time was one to produce experts to advise on policy, not leaders to make policy. With modifications, accretions and improvements, that pattern has persisted ever since.

Regarded as a preparation for doing nothing but organic chemistry, or non-ferrous metallurgy, or light electrical engineering—in other words, regarded as a production line for highly differentiated experts—there is nothing much wrong with technological education in Britain. However, grounds for anxiety do exist, for buried at the foundations of our system for educating higher technologists there are two assumptions, both of which are wrong. The first assumption is that the technologist has had a balanced schooling with a thorough grounding in what are vaguely called the 'humanities'. The second assumption is that the technologist is to become and to remain an expert to serve the manager, never to become a manager himself. Because these two assumptions are still made, the question of including the humanities in higher technological education is still not taken seriously.

Contrast this with the training being given to technologists in other countries. The student at the Massachusetts Institute of Technology must devote a considerable portion of his time throughout all four years of his course to English composition and literature, history, psychology, international relations and economics; and these subjects are taught in a way which is relevant to technologists. In the Swiss Federal College of Technology at Zurich, third- and fourth-year students include in their course law, economics and management, and there is a Department of General Education with twelve professorships covering foreign languages, philosophy, history, law and political economy. In the Technical University of Delft, there is a so-called *Studium Generale*, which provides lectures on religion, philosophy, music and art. Even technological institutions in the Soviet Union devote some time to the humanities and the social sciences[2]. The British Commonwealth has not ignored these examples: in the New South Wales University of Technology there is a Department of Humanities, with a full professor at its head. Even some English technical colleges have introduced an element of the humanities into their courses[3]. Nevertheless, universities in Britain are not yet persuaded that the humanities are an essential ingredient in higher technological education. Many universities do indeed arrange opportunities for students to broaden their interests through voluntary attendance at lectures on art and music and the like. This is admirable, but it is a very different thing from recognizing certain humanistic studies as an integral part of a technologist's formal higher education.

Let us be quite hard-headed about the humanities which should be included in higher technological education. There are four criteria for selecting them. First, they should not include subjects which can and ought to be taught at school. Second, they should be taught as genuine humanities, that is to say, they should deal with the creative and social acts of man, and particularly with value-judgments about these acts: man's ideas of right and wrong, of good and evil, of justice, freedom and government. Third, they should be taught in such a way as to be relevant to the contemporary world and to technology. Fourth, humanities at this level of teaching should be instruments to enhance the individuality of students, to resist that levelling of differences in taste and personality, that tendency to increase social entropy, which is a melancholy consequence of the modern techniques of mass communication.

Indeed, what is needed is nothing less than a revision of the idea of a liberal education. The "Oxford Dictionary" defines liberal education as education fit for a gentleman. That is still an acceptable definition; it is the idea of a gentleman which has changed. A century ago, when Britain awoke to the need for technological education, a gentleman belonged to what was called the leisured class. The occupations of his leisure did not require any knowledge of science or technology. Modern gentlemen do not belong to the leisured class. Many of them work something like a seventy-hour week, and more and more of them are finding that their business requires expert knowledge. Even members of the House of Lords find themselves called upon to make decisions about radioactive fall-out and overheating during supersonic flight and the strontium content of bones. Dare I suggest that, in order to be a gentleman nowadays, one has to be something of a technologist?

But technology alone will not make a modern gentleman. It is nothing new to suggest that technologists should know something of the humanities. I want to go farther; I want to suggest that certain of the humanities are an integral part of technology. 'Technological humanism' is not just a rhetorical phrase: it has genuine content.

For technology is inseparable from men and communities. In this respect technology differs from pure science. It is the essence of the scientific method that the human element must be eliminated. Contrary to the assumptions of some people, science does not dispense with values; but it does eliminate the variability of human response to values. It concerns itself only with phenomena upon which all qualified observers agree. It describes, measures and classifies in such a way that variation due to human judgment is eliminated.

Unlike science, technology concerns the applications of science to the needs of man and society. Therefore, technology is inseparable from humanism. The technologist is up to his neck in human problems whether he likes it or not. Take a simple example: the civil engineer who builds a road into a new territory in tropical Africa. He may assert that it is not his business to take into account the effect his road will have on primitive villages up-country; but his road is in fact a major experiment in social anthropology. He does not need to be a professional anthropologist, but he cannot afford to be utterly ignorant of the implications of his work. He is a technologist, not a pure scientist: the social consequences of his work are therefore an integral part of his profession.

Long ago, in "Science and the Modern World", A. N. Whitehead saw the essential unity between technology and humanism. He said: "A factory with its machinery, its community of operatives, its social service to the general population, its dependence upon organizing and designing genius, its potentialities as a source of wealth to the holders of its stock is an organism exhibiting a variety of vivid values. What we want to train is the habit of apprehending such an organism in its completeness".

The habit of apprehending a technology in its completeness: this is the essence of technological humanism, and this surely is what we should expect an education in higher technology to achieve. How is it to be achieved? Ninety years ago, when Thomas Henry Huxley was giving evidence before a Select Committee on Scientific Instruction, he poured scorn on the universities because they made literature and grammar the basis of education and (as he put it) "they actually plume themselves upon their liberality when they stick a few bits of science on the outside of the fabric". It will not do for us, ninety years later, to reverse the process and to plume ourselves upon our liberality when we stick a few bits of the humanities on the outside of the fabric of higher technology. It should be our business in higher technological education to persuade students that they cannot practise technology without continually reflecting upon its social implications, and that some understanding of the humanities is essential to this reflexion. For a metallurgist to take a course in general history in order to acquire a little culture is an innocent but not necessarily a very profitable amusement. But if the metallurgist studies the social and economic history of the Industrial Revolution; if he learns how the making of iron followed the forests across Europe until coal replaced charcoal; if he realizes how mining and the building of railways and canals stimulated the study of geology, and how this in turn brought men face to face with the evidence for organic evolution; if he considers the effect which the introduction of electric power has had on the distribution and lay-out of factories, and the effect which aluminium alloys have already had (through air transport) on the conduct of diplomacy: then history becomes integrated with metallurgy; his humanism becomes a relevant part of his day-to-day thinking.

What does all this involve in, for example, the weekly time-table of a civil engineer in a British university? It involves a little more time in the undergraduate course, secured either by cutting some subjects down or by lengthening the course. Since Britain is about the last country in the world to attempt to train technologists in three years from the post-intermediate stage, I would not regard this as a very grave obstacle. It involves a little more money. Since it costs £45,000 to train a bomber pilot and about £1,500 to train a technologist, I would not regard some additional cost as a grave obstacle either. It involves some newly designed courses which are within the capacity of lecturers normally to be found in faculties of arts, law and economics.

Here are some examples of the choice of courses these lecturers might offer to technology students: (*a*) a course on ethics and jurisprudence, with some discussion of the principles of law and justice (such as might be given by a legal philosopher); (*b*) a course on industrial and social history of Europe since the seventeenth century, with emphasis on the social effects of technological change (such as is already offered at the Dutch Institute of Social Studies at The Hague); (*c*) a course on political theory, political institutions and the history of guilds and trades unions (this would be an opportunity for medieval as well as modern historians); (*d*) a course on industrial psychology; (*e*) a course on sociology and social anthropology ; (*f*) a course on the history of technology, including readings from the classics of science and technology (this might go some way toward meeting one criticism of all present courses on technology, namely, that it is possible to get a first-class honours degree without ever having read a work of genius) ; (*g*) a course on linguistics and communication (a development of some of the material contributed to the Communication Research Centre at University College, London).

All industrial peoples have to solve a great problem in human ecology, namely, how to adapt themselves, through the second channel of inheritance, to the social climate which is being created by modern technology. Technologists have a special responsibility to solve this problem for themselves and to reflect on its implications for their fellow citizens. The solution for technologists lies through the inheritance of education they receive. The appropriate education for higher technology should be one which does for contemporary civilization what our traditional classical education has so successfully done for the civilizations of Greece and Rome.

CHEMICAL TRANSMISSION OF NERVE IMPULSES IN VERTEBRATES AND INVERTEBRATES

BEGINNING with the presidential address of Sir Lindor Brown on the subject of chemical transmission at nerve endings, Section I (Physiology and Biochemistry) of the British Association, at the recent meeting in Dublin, devoted its first two sessions to many different aspects of this problem. The president's address combined a simplicity of language with a remarkable amount of information about the intricate mechanisms which are concerned in ganglionic and neuro-effector transmissions. The next speaker (Dr. Catherine O. Hebb, Agricultural Research Council, Cambridge) dealt specifically with the occurrence of cholinergic nerve fibres in the central nervous system. These have been identified by the distribution of enzymes controlling acetylcholine metabolism. As a background for this study, evidence was cited to show that choline acetylase and acetylcholine exist together in the same tissue particles or organelles, which are probably not the mitochondria. This distribution of acetylcholine is in agreement with ideas expressed earlier by Katz and his co-workers.

The immediate relevance of this work is in showing that the distribution of choline acetylase is probably the most reliable guide to the distribution of cholinergic neurones. In the central nervous system, these are to be found in sensory pathways as the second-order neurones ; in the case of the visual and auditory pathways, they form the fourth-order neurones as well. Other points emphasized were that all the afferents to the caudate nucleus in man as well as other mammals appear to be cholinergic, that no cells arising within the cerebellum are cholinergic and finally that the proportion of cholinergic neurones has become greatly reduced in the cerebral neocortex as it has enlarged during the course of the evolution of the higher mammals.

Dr. H. Blaschko (Oxford), who followed, described the very complex metabolic route which leads ultimately to the formation of noradrenaline and adrenaline. Not all the enzymes concerned in the necessary transformations are as yet known, but the past few years have seen very considerable progress in identifying the precursors of these two amines. One of these is dopamine, and the point was made that in view of the large amounts of this substance which are stored in adrenergic nerves it could have some function other than as a precursor of adrenaline and noradrenaline.

The second part of Dr. Blaschko's talk concerned the tissue storage of adrenaline and noradrenaline. This occurs in tissue organelles (separate from one another), which are typical of adrenal medullary or other chromaffin tissue and which are characterized by their high density. They can be distinguished from the mitochondria as they contain none of the respiratory enzymes.

The interesting feature of this storage is that the organelles containing the two amines also contain adenosine triphosphate in amounts which would be expected (1 mol. adenosine triphosphate to 4–5 mol. amine) if all of the amine present is bound to the triphosphate.

It could be that the events set in train by the arrival of a nerve stimulus lead through the activity of adenosine triphosphatase (also abundant in the adrenal medulla) to breakdown of the adenosine triphosphate and hence to the release of the stored adrenaline or noradrenaline.

Beginning the second session, held jointly with Section D (Zoology), Dr. D. B. Carlisle (Marine Biological Association, Plymouth) spoke about his search for the identity of the transmitter which is released from the pericardial organs of the crab's heart. Experiments on other Crustacea also contributed to his conclusions. The nature of the pericardial organs of the crab has only become apparent in the past few years ; it appears that they consist largely of efferent nerve endings, and these lie wholly immersed in blood in the pericardial space. The material which they release can be detected downstream to them in the blood flowing into the heart. On the isolated heart of the edible crab, the active material obtained either as an extract of the pericardial organs or from the blood flowing away from them increases both the amplitude and frequency of the beat ; while in the spider crab increased amplitude is combined with slowing of the heart-beat. Of a number of cardiac stimulants tested, only 5-hydroxytryptamine came near to reproducing these responses precisely ; other evidence, however, including paper chromatographic analysis, indicated that the material was not likely to be 5-hydroxytryptamine. Instead, there are various pointers to suggest that 5,6-dihydroxytryptamine is the transmitter. While this view has not yet been tested beyond doubt, it provides the best explanation of all the experimental evidence now at hand.

Dr. O. F. Hutter (University College, London) was concerned with the mechanisms which underlie cardiac inhibition by acetylcholine or vagal stimulation. He showed first, by means of recordings from intracellular electrodes, that the cardiac action potential (accompanying systole) in pacemaker fibres is curtailed or abolished by the inhibitory stimulus. The explanation is that the membrane resistance of sinus fibres is lowered by acetylcholine; this is indicative of a change in permeability to ions that normally contribute to the resting potential. Both chloride and potassium ions may be involved, but experiments with radioactive isotopes indicate that the change of permeability is specific for potassium ions.

Dr. Hutter concluded by suggesting that acetylcholine brings about these effects by acting on specific receptors which are abundant in the regions of the pacemaker and probably, too, at the atrio-ventricular node; but are absent from ventricular and Purkinje tissue.

The problem of inhibition by a chemical transmitter was also dealt with by Dr. P. Fatt (University College, London), who pointed out the analogies existing between the specific inhibitory fibres of some crustacean muscles and the fibres which inhibit discharges from the anterior horn cell of the mammal. Analysis of experiments done earlier with Prof. B. Katz on the effects of combined stimulation of the inhibitory and excitatory fibres has led them to conclude that the transmitter of the inhibitory impulse acts (1) competitively to displace the excitatory substance from the tissue receptors, and (2) by a direct action on the membrane.

Dr. Fatt considered that the same ideas could be applied in explanation of the inhibition of the anterior horn cells of the mammalian spinal cord. In an analysis of this inhibition he showed that the electrical change (whether in the direction of hyper- or de-polarization) is conditioned by the level of the negative potential of the cell above its resting value. Similarly, experimental increase in the intra-cellular chloride ions reverses the hyperpolarization response to one of depolarization. Sulphate ions are inactive in this respect. Dr. Fatt's conclusion was that inhibition of the anterior horn cell is due to an increase in permeability to chloride ions. Whether permeability to potassium ions is also affected is difficult to determine. In crustacean muscle, however, it appears that the permeability to both potassium and chloride ions is affected. In a later discussion, Dr. Fatt said that the inhibitory substance concerned in these effects might be γ-amino-butyric acid, since it has been reported by other workers that this is the inhibitory substance of crustacean muscle and it also has inhibitory effects on the vertebrate central nervous system. In a preliminary experiment he had himself found that γ-amino-butyric acid does reduce the membrane resistance of crustacean muscle fibres, thus supporting the suggestion that it may be the inhibitory transmitter. Dr. Hutter made the point that this substance is an anion, which may in some way account for the fact that it increases membrane permeability to chloride ions, whereas acetylcholine, which is a cation, does not.

Dr. J. S. Gillespie (University College, London), in the concluding paper, described his experiments to determine the rate of liberation of noradrenaline from the sympathetic fibres innervating the spleen. The chief interest of his communication was that it provided evidence showing that relatively large amounts of noradrenaline are taken up by the tissue receptors. This effect is unmasked by the administration of agents which block the receptors. With this treatment it is possible to demonstrate the release of noradrenaline from a number of other sympathetic nerves, whereas in the absence of blocking agents it is only from the splenic nerve effluent that detectable amounts of noradrenaline can be recovered.

One of the interesting features of these two sessions was the great diversity of techniques which had been employed by the various authors. It was interesting, too, to reflect how much more important the concept of chemical transmission has become in the past few years and how much more widely it is now applied. Certainly it is no longer a concept which is understood by the few and ignored by most physiologists. Instead it seems to have become a meeting point for physiologists whose interests are otherwise entirely diverse.

CATHERINE HEBB

RADIATION AND BIOLOGY

ON September 9, in Dublin, Sections D (Zoology), I (Physiology and Biochemistry), K (Botany) and M (Agriculture) of the British Association held a joint session under the chairmanship of Prof. D. G. Catcheside, on radiation and biology.

Mr. J. L. Putman, of the Atomic Energy Research Establishment, Harwell, opened the session with a paper entitled "The Physical Basis of Radioactivity". In it he reviewed the development of the subject in the sixty-one years since Becquerel's discovery, touching upon some of the modern applications of radioactive materials. His talk was essentially an introduction which lucidly prepared the way for the papers which followed.

The paper read by Mr. R. N. K. Whitehouse, of the Plant Breeding Institute, Cambridge, was entitled "Radiation-induced Mutations in Crop Improvement". It was both a review and assessment of the progress that has been made, and an attempt to forecast what the future may hold. To assess the value of radiation as a source of new mutation, it is necessary to consider what progress might have been made without it, by the classical methods of the plant-breeder, namely, selection with or without hybridization. It is perhaps not realized sufficiently often that exposure to radiations can only induce new genetic variability; by far the greater part of any plant-improvement programme, whether based on natural or on induced variability, consists of the subsequent breeding and selection.

'Mutation breeding' has been used with three classes of crop plant: self-pollinators, cross-pollinators, and plants that normally reproduce vegetatively. It is among the self-pollinators, which are genetically homozygous, except at loci at which mutation has occurred in recent generations, that selection without mutagenic treatment may be expected *a priori* to be least effective; and in point of fact it is with this class of plant that mutation breeding has been most used. Very few mutation-bred strains have yet reached the market, but this is partly because insufficient time has elapsed. In Sweden, two mutant strains of barley with valuable new characteristics are now being multiplied for marketing: one has short straw and the other is both early and short-strawed. Strains with improved straw strength and mildew resistance have been reported from Germany and Austria, and one of these is now being multiplied for the market. Rust-resistant wheat and oats have been reported from the United States. Among non-cereal crops, a cooking pea with improved yield has already been marketed in Sweden, and improved peanuts are being developed in the United States. It is too early yet to assess the full value of the method with plants which are normally self-pollinating, but it is quite possible that its main value may yet prove to be in combination with hybridization of such plants.

Cross-pollinators commonly have such an abundance of genetic variability available that the plant-breeder has not often considered it necessary to increase it by irradiation. However, mutation breeding has been used successfully in Sweden to provide strains of white mustard and of rape with increased oil content, and is now being used with various other plants, including sugar-beet. For the third main class of plant, those normally reproducing vegetatively, there have been no reports yet of useful induced-mutant strains. Work on fruit trees is in progress in the United States, Sweden and Germany, as well as England; one of the difficulties is that the breeder is dealing with an irradiated population of cells, as in a woody shoot, and there may be differential viability between the normal and mutant cells, with subsequent elimination of the latter. Repeated cutting back of new growth, thereby stimulating the growth of dormant buds, may, however, help to overcome this.

Looking into the future, Mr. Whitehouse visualized the conditions under which the use of radiation-induced genetic variability may prove valuable. He listed five: (1) where it is desired to add a single character to a delicately balanced genotype, as with rust resistance in oats; (2) in vegetatively propagated plants, where sexual reproduction will destroy the characteristics of the variety; (3) where a desirable gene is known to exist, but is unobtainable for biological, geographical or political reasons; (4) to extend the range of variability of a variable character in a sexually reproducing plant; (5) in special problems such as breaking close linkage or transferring characters through chromosome fragmentation. However, though irradiation is already proving a valuable tool for the plant breeder, it is by no means a panacea for all ills; and though it may speed selection, it does not and cannot eliminate the need for large breeding programmes. Valuable mutants occur, but the great majority, by far, are detrimental.

Dr. N. G. Trott, of the Royal Marsden Hospital, spoke about "Radioactivity—its Hazards and Benefits to Health". As a hospital physicist, he reviewed first the history of radiation protection measures, from the recommendations of the British X-Ray and Radium Protection Committee, thirty-six years ago, to the recent recommendations of the International Commission on Radiological Protection. Present-day protection procedures are based largely on knowledge gained through unwitting malpractice in the past: uranium miners who developed lung cancers, dial-painters who licked their paint-brushes and afterwards developed bone cancers, and radiologists who developed skin cancers or leukæmia, all contributed to the knowledge on which present-day safety precautions depend. Dr. Trott described and illustrated some of the means of controlling the radiation environment and measuring the radiation which reaches the human body: space monitors, film badges, counters, glove-boxes, lead and concrete shielding, and all the paraphernalia of a radiation laboratory. The success of such methods, if rigorously applied, is shown by the fact that none of the staff of the United Kingdom Atomic Energy Authority receives more than the maximum permissible dose of radiation, as defined by the International Commission on Radiological Protection, and 90 per cent receive only up to one-tenth of the permissible maximum.

Clinical applications of radioactive isotopes are increasing rapidly; they find use both in diagnosis and in therapy. In diagnosis, very small quantities of short-lived isotopes are injected into or ingested by the patient, and their course is followed by means of very sensitive radiation detectors, especially scintillation counters. Sodium-24 has many applications in studies of blood circulation; iodine-131 in thyroid disorders; chromium-151 in the measurement of red cell volumes; and cobalt-58 in the diagnosis of pernicious anæmia.

Radioactive isotopes for use in therapy may be applied externally or internally. Before the War, the only established practices involved the use of solid sources containing radium or radon, a technique suggested so long ago as 1903 by Alexander Graham Bell. The availability of artificially active isotopes has greatly extended the range of practice. For external irradiation there are now beams from telecurie cobalt-60 and cæsium-137 sources. Materials for internal solid sources and applicators now include strontium-90, tantalum-182 and gold-198. Radioactive gold may be used also in colloidal form, in which it remains localized in the body cavities or tumours. Materials for transport to the tumour site in solution include iodine-131, which is localized in the thyroid and used for therapy of thyroid tumours, and phosphorus-32, which is now widely used in the treatment of polycythæmia vera. The use of artificial radioactive isotopes in therapy is a field in which rapid advances are being made; constant watchfulness will be necessary to ensure that we do not, over the next few decades, find ourselves presented with a correspondingly rapid advance in observations of radiation carcinogenesis; the clinician and the health physicist must form an indivisible team.

The fourth paper in the symposium was also on an aspect of radiation protection: Dr. T. C. Carter, of the Medical Research Council's Radiobiological Research Unit at Harwell, spoke about the genetic hazards of radiations under the title "Ionizing Radiations and the Socially Handicapped". There are two approaches to the problem of genetic damage to man: the synthetic and the analytical. In the synthetic approach an attempt is made to estimate (*a*) the number of gene loci in a human haploid set, (*b*) the rate of induction of mutation per gene per röntgen exposure, and (*c*) the average number of mutant genes lost per 'genetic death'. For a population in genetic equilibrium, the rate of acquisition of mutant genes, by spontaneous or induced mutation, must be equal to the rate of elimination by genetic death. Hence the number of genetic deaths induced by a given radiation exposure can be calculated if (*a*), (*b*) and (*c*) are known. The difficulties of estimating (*a*), (*b*) and (*c*) for man are, however, so great that some alternative approach is desirable.

The analytical approach has four steps. It starts with an estimate of the number of handicapped individuals in a human population. In Great Britain, for example, there are about 250,000 diabetics, 210,000 congenitally malformed, 170,000 mentally ill, 106,000 blind and 22,000 deaf-mutes. All these conditions, among many others, are known to have some genetic element in their ætiology, and the second step is to estimate its magnitude; thus about half the blind (53,000) owe their affliction to genetic constitution, and about two-thirds of the deaf-mutes (15,000). The third step is to assess the extent to which these genetically afflicted owe their genetic constitution to mutation induced, in the past, by naturally occurring radiations; this is equivalent to assessing the natural radiation dose received per generation by man—about 3 r. in Great Britain—and the dose ('doubling dose') required to induce mutation equal to the spontaneous mutation. There are several lines of evidence that the latter may be about 30 r., in which case about one-tenth of human mutation is due to natural radiations. The fourth step is to assess the extent by which modern practices have increased radiation exposure. For Great Britain a lower limit only is known; the total is at least 0·7 r., almost all of which is due to diagnostic radiology. Reports from Sweden and the United States have given estimates of about 3 r. and 4·6 r. respectively. If the Swedish figure is applicable to Great Britain, the additional exposure is about equal to the exposure from natural radiations, and the human mutation-rate in Britain will have been raised in the past sixty years by about 10 per cent. In that event the genetic component of the handicapped group of our population will eventually, if exposure continues at the present rate, rise by about 10 per cent also; this would imply an additional 5,300 blind, 1,500 deaf-mutes, etc. These estimates are necessarily rough; their justification lies in the fact that in deriving them some of the gaps in present-day knowledge are exposed; they show some of the places where additional research is needed.

PROBABLE EVOLUTIONARY RELATIONSHIP OF SEROTONIN AND INDOLEACETIC ACID, AND SOME PRACTICAL CONSEQUENCES THEREFROM

By DR. D. W. WOOLLEY*

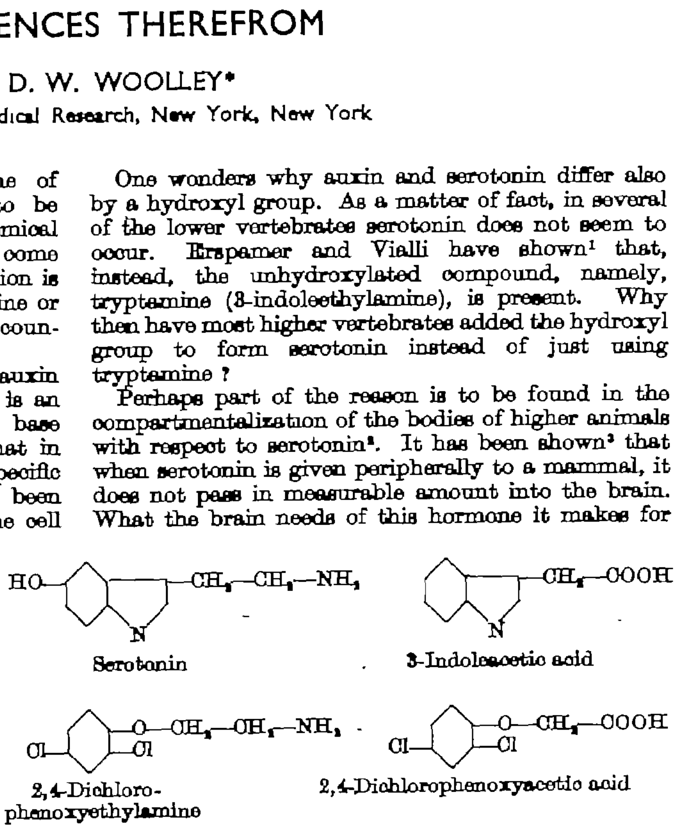
Rockefeller Institute for Medical Research, New York, New York

ALTHOUGH the natural growth hormone of plants (auxin) has long been known to be 3-indoleacetic acid, the hormone of similar chemical structure in the animal world has just recently come to light. The first purpose of this communication is to point out that serotonin (5-hydroxytryptamine or 5-hydroxy-3-indoleethylamine) is possibly the counterpart in animals of auxin in plants.

The structural resemblance of serotonin to auxin is clearly evident (Fig. 1). The fact that one is an acid whereas the other is the corresponding base which has been hydroxylated may suggest that in the course of evolution the usefulness for specific purposes of the indolic structure has long been recognized by Nature. In plants, in which the cell sap is usually acidic, the acid (that is, auxin) has been evolved, whereas in animals, in which the juices are usually somewhat alkaline, the corresponding base has proved to be more useful. In both situations the hormone would exist predominantly unionized. This may be of great importance in the physiological functioning of these compounds. If indoleacetic acid were the form used by animals, it would exist almost exclusively as the ion at the *p*H of most cells.

One wonders why auxin and serotonin differ also by a hydroxyl group. As a matter of fact, in several of the lower vertebrates serotonin does not seem to occur. Erspamer and Vialli have shown[1] that, instead, the unhydroxylated compound, namely, tryptamine (3-indoleethylamine), is present. Why then have most higher vertebrates added the hydroxyl group to form serotonin instead of just using tryptamine?

Perhaps part of the reason is to be found in the compartmentalization of the bodies of higher animals with respect to serotonin[2]. It has been shown[3] that when serotonin is given peripherally to a mammal, it does not pass in measurable amount into the brain. What the brain needs of this hormone it makes for



Serotonin 3-Indoleacetic acid

* With the technical assistance of Sara Kauffman and Elnora Van Winkle.

itself, and what the periphery needs it makes for itself. The behaviour of an animal, and presumably therefore its mental state, is influenced by changes in the serotonin-content of the brain[2-4]. Because this hormone is being formed at a variable rate in the periphery, as, for example, it is increased when blood platelets are ruptured, the animal's behaviour as controlled by the brain would be constantly at the mercy of these fluctuations in peripheral serotonin if there were free passage of it from periphery to brain. It is possible that the insertion of a hydroxyl group into the molecule is a device which has been evolved for retarding the passage of serotonin from blood to brain. It is well known that various phenols enter and act upon the central nervous system less readily than do the corresponding compounds which either are not hydroxylated, or which have the phenolic group protected by conversion into a methyl ether. It would therefore represent an evolutionary gain to an animal thus to be able to protect its brain (and its behaviour) against the fluctuations in peripheral serotonin. Be this as it may, the fact is that in most higher animals which have been investigated, serotonin, and not tryptamine, occurs, although injected tryptamine exhibits many serotonin-like properties. In some of the lower forms one finds either both compounds, or, occasionally, just tryptamine. The reasons why this should be so can only be guessed.

If serotonin is the counterpart in the animal world of 3-indoleacetic acid in the plant world, then we might possibly expect to find some similarity in the basic biochemical roles of these two substances. We need not necessarily require that this be found if we follow Darwin's original dictum that in the process of natural selection old equipment is frequently put to new uses. Nevertheless, if a common role for serotonin in animals and auxin in plants were to be found, it would lend support to the thesis of this communication. Actually, although the biochemical roles of neither substance are understood, enough is known to suggest that perhaps they do have much in common.

Indoleacetic acid causes plant cells to grow, that is, to elongate, because it increases the uptake of water. Many recent studies have suggested that the hormone changes the permeability of the plant cell wall, and that the uptake of water is to be ascribed to this action (see, for example, ref. 7). Several studies also suggest a relationship of this effect to the passage of magnesium ions and possibly other metallic ions.

Less is known about the action of serotonin because it was discovered so recently; but yet there are studies which suggest that it may have much to do with permeability. In this light the experiments of Pickles and Sutcliffe[8] are of interest. They found that serotonin (or indoleacetic acid) changed the permeability of the cells in slices of beetroot so that the red pigment was released into the surrounding medium. By contrast, there was retention of sodium ions. There is as yet no evidence that serotonin occurs in beets, but it has been detected in at least one plant, namely, cowhage[9]. Among the fungi[10] and in the cohoba bean[11], *N*,*N*-dimethylserotonin, or bufotenin, has been proved to exist by actual isolation.

When one turns one's attention to the functions of serotonin in animals, one sees first that the outstanding property of this hormone is to cause smooth muscles to contract. Does this action depend upon changes of cell permeability? Although practically nothing is known about the biochemical reasons why serotonin, or for that matter, why adrenalin or acetylcholine, makes muscles contract, the ideas and experiments of Csapo[12] on the actions of some of these hormones on muscles warrant attention. Csapo points out that hormones such as adrenalin or acetylcholine do not cause isolated filaments of actomyosin to contract. The only substances which contract these fibres are calcium or magnesium ions in the presence of adenosine triphosphate. Perhaps, then, the action of hormones such as acetylcholine is to make the membrane of the muscle cell wall permeable to these ions. One could think about serotonin in a similar fashion, as opening a special valve (not the same as the valve opened by acetylcholine) which admits such ions to the muscle cell. This is, of course, merely a working hypothesis. Nevertheless, data exist which show that serotonin given to whole animals does cause the retention of metallic ions such as sodium ions[13], although the site of this action and its mechanism are not understood. Such findings prompt one to study the effects of serotonin on permeability of animal cells.

If we pursue for a moment the idea that serotonin is to the animal some of the things which indoleacetic acid is to the plant, then some consequences of practical importance soon appear. The striking lack of specificity of chemical structure needed for plant-growth activity is well known. Indoleacetic acid, which is expensive to make, can be replaced by such cheap compounds as 2,4-dichlorophenoxyacetic acid and by many others. Although 2,4-dichlorophenoxyacetic acid acts like indoleacetic acid in some test systems, in others it acts antagonistically to the hormone. Concentration is also an important variable in deciding its effects on a given plant tissue, and certainly it does not mimic in all respects the actions of the natural hormone. Nevertheless, the use of 2,4-dichlorophenoxyacetic acid and similar compounds as herbicides is intimately linked to the ability of these relatively cheap chemicals to react with the plant cell receptors which normally appear to unite with indoleacetic acid.

If our concept is correct, we would expect the amines corresponding to 2,4-dichlorophenoxyacetic acid and its relatives to be able to do in animal tissues some of the things which serotonin normally does. We would expect these amines to act like serotonin on some tissues and perhaps to act as specific antagonists of serotonin on others. We would expect qualitative differences between serotonin and these phenoxy compounds on those tissues for which the analogues mimic the hormone. Finally, the relationship of structure to activity among the phenoxy compounds might parallel in animal tissues what is known from studies with plants. We might thus anticipate that 2,4-dichlorophenoxyethylamine would be more active on animal tissues than a para-substituted congener. In the plant world, 2,4-dichlorophenoxyacetic acid usually proves to be more active than a congener such as *p*-chlorophenoxyacetic acid. These expectations have all been realized. Their practical significance is akin to the practical reasons for the use of 2,4-dichlorophenoxyacetic acid. Serotonin and its antimetabolites have come into prominence recently as potential drugs for the treatment of several diseases of man[3,4,14]. It may be that some of these readily available and cheap compounds which have now been shown to act as antiserotonins, or like

Table 1. ACTIVITY OF VARIOUS PHENOXYETHYLAMINES AS PRO- AND ANTI-SEROTONIN

Phenoxyethylamine hydrochloride	Serotonin-like potency*	Antiserotonin potency†
2,4-Dichloro-	1	150
2,4,6-Trichloro-	10	100
4-Methoxy-	0·1	1,500
2,6-Dimethoxy-	0·5	90
3,4,5-Trimethoxy-	1	200

* Measured on clam heart and expressed as a percentage of the activity of serotonin creatinine sulphate.

† Measured on rat uterus and expressed as the quantity of compound required to overcome the action of a unit weight of serotonin creatinine sulphate. The smaller the inhibition index, the more potent is the compound as an antiserotonin.

serotonin, will find use in medicine, and may even be made superior to existing antiserotonins.

The series of compounds used in this study was made in either one of two ways. In the first, a suitable phenol was condensed with chloroacetamide, and the resulting phenoxyacetamide was reduced with lithium aluminium hydride to the amine. In the second method, which was more suitable for large-scale operations, the phenol was condensed with ethylene bromide, and the resulting phenoxyethylbromide was aminated with alcoholic ammonia. Since all these methods are well enough known to be standard procedures in organic chemistry, they need not be described here in detail. Suffice it to say that the use of sodium ethoxide in absolute ethanol for the reaction of the phenols with the chloroacetamide or ethylenebromide was necessary in most cases. The hydrochlorides of the final amines were crystallized from alcohol by the addition of ether.

To test for serotonin-like activity the heart of the clam *Venus mercenaria* was used as described by Welsh[14]. Quantitative comparison of each compound with serotonin was made on a number of individual hearts and results were averaged. These results are summarized in Table 1. The serotonin-like activity of these phenoxyethylamines was qualitatively different from that of the hormone itself. The response to serotonin (that is, the increased amplitude of beat of the heart) developed very soon after application of the hormone. With the phenoxy compounds the response was slower, and it was usually necessary to wait for about fifteen minutes before the maximal effect was seen. It then proved rather difficult to wash the heart free of these compounds. The 3,4,5-trimethoxy compound was especially difficult to wash out. The 2,4-dichlorophenoxyethylamine was interesting in that, although with most hearts it had about 1 per cent of the potency of serotonin on a weight basis, some hearts were found for which it was much more active. Thus in one it showed 30 per cent of the activity of serotonin, and in another 10 per cent. These values compare surprisingly well with the relative potencies of 2,4-dichlorophenoxyacetic acid and indoleacetic acid in some plants.

The clam heart method was selected for the tests of serotonin-like action because recent experience has shown that such invertebrate tissues frequently will reveal serotonin-like activity in several structural relatives of the hormone, whereas mammalian tissues such as isolated rat uterus or sheep carotid arteries show such compounds to be only antimetabolites with no serotonin-like effects[2,15,16]. Presumably the receptors for serotonin differ in the degree of specificity required to actuate them (cf. ref. 16).

One may ask whether the effect of the phenoxyethylamines was really serotonin-like or whether any arylalkylamine would show such activity. To answer this question, noradrenalin was tested. It was found not to produce a serotonin-like action in concentrations similar to those found effective with the phenoxy compounds.

The tests with isolated rat uteri were performed as described earlier from this laboratory[17]. The results are summarized in Table 1. On this tissue none of the compounds showed serotonin-like activity, but instead all proved to be antiserotonins. Their action in this latter respect was quite specific, as shown by the fact that they did not antagonize the action of acetylcholine on this organ. Just as in the tests with the clam heart, several of the analogues, especially the 3,4,5-trimethoxy one, exhibited a prolonged action on the uterus in that even after many washes the tissue did not respond to serotonin. Its responsiveness to acetylcholine, however, was not impaired. The antagonism between serotonin and one of the analogues, namely, 2,6-dimethoxyphenoxyethylamine, was studied over a range of concentrations of the hormone in order to find whether or not it was competitive. It was found to be so.

These compounds were tested for ability to act as antimetabolites of serotonin in living animals, because it is well known that many antagonists which are effective on isolated tissues fail in the living animal. Prevention of diarrhoea in mice injected with 5-hydroxytryptophan was the test[18]. The 2,4-dichlorophenoxyethylamine at 2 mgm. per mouse was inactive in this test. The 2,6-dimethoxy compound was active in prevention of the diarrhoea, but the most potent substance was the 3,4,5-trimethoxy derivative. Perhaps the irreversible nature of its antiserotonin action as described above contributed to its effectiveness (cf. ref. 14).

One prediction that was made from the experiences in plants with congeners of 2,4-dichlorophenoxyacetic acid was not borne out in the tests on animal tissues with the present phenoxyethylamines. Foster *et al.*[19] have stated that, when a phenoxyacetic acid is substituted in both the 2 and 6 positions, it shows in plants no hormonal activity; instead, only anti-indoleacetic acid activity is found. One might expect this situation also to apply to the animal tissues treated with these phenoxyethylamines. This did not prove to be so. Substitution in both positions 2 and 6 did seem to enhance potency as an antiserotonin when tested on the rat uterus, but it also increased (or at least did not abolish) serotonin-like activity for the clam heart. However, it is not so surprising to see this one difference as it is to witness how many of the results with plants are borne out by the findings in animal tissues.

The lack of specificity of structure required for plant-growth hormone activity is certainly one of the striking features which one must bear in mind when thought is given to the concept of extreme specificity of biological reactions. Such concepts of specificity have enjoyed a golden age of acceptance, especially when the results with the water-soluble vitamins seemed to bear them out so well. The mental picture based on these concepts is being challenged or modified more and more in the light of such phenomena as the lack of specificity of indoleacetic acid and of the œstrogenic hormones. We must now add serotonin to the list, because a number of compounds now exist which have been shown to possess actions like it if the test objects are properly chosen. Not so much because a similar molecule such as tryptamine has the activity, but because something far removed such as 2,4-dichlorophenoxyethylamine does, the problem about specificity seems urgent.

OBITUARIES

Prof. Carl Störmer, For.Mem.R.S.

We regret to announce the death, on August 13, of Fredrik Carl Mülertz Störmer, renowned for his observational and theoretical studies of the aurora borealis. He was born on September 3, 1874, at Skien, Norway. He attended the University of Oslo (then Kristiania) during 1892–98. Later he studied at Paris, 1898–1900, and also, as a *Privatdocent* on leave from Oslo, at Göttingen in 1902. In 1903, at the early age of twenty-nine, he became the professor of pure mathematics at Oslo; this post he filled for the remainder of his official career. Between 1895 and 1903 he had published numerous mathematical papers, on series, the theory of numbers, and the theory of functions.

But in the year of his professorial appointment, his colleague, Prof. K. Birkeland, showed him a series of beautiful experiments on the movements of cathode rays in magnetic fields, particularly in the field of a magnetized sphere or magnetic dipole. This event permanently diverted Störmer's thoughts and research interest from pure mathematics to auroral theory. He knew that Poincaré had integrated the equations of motion of a charged particle in the field of a magnetic pole. This, and the experiments by Birkeland, impelled him to study mathematically the motion of a charged particle in the field of a magnetic dipole.

In 1904 he published the first of a series of papers on such trajectories. He found first integrals of the equations of motion, from which he was able to draw valuable and illuminating inferences. The complete solutions required numerical integration. Over many years he made or organized such calculations, and found a great variety of paths; his papers on this subject were continued until 1950, and constitute a major part of his life's work.

A second major part of Stormer's contribution to science began in 1909. He wished to compare his results with observation. For personal reasons he had mastered the photographic art, and he decided to apply his knowledge to auroral observation. His object was to determine the form and the position of auroras in space—namely, their height and their location in plan. This required simultaneous photography from two or more well-separated sites, connected by telephone. The Norwegian postal authorities gave him special facilities for telephonic communication, and he gained the aid of distant assistants. Thus he placed our knowledge of the situation of auroras on a firm foundation. Most of our present knowledge of this subject is due to him, though his example stimulated his Norwegian colleagues Vegard, Krogness and Harang to add further valuable contributions. In 1913 Störmer made an expedition to Bossekop in northern Norway for such work near the auroral zone. Later, until almost the end of his life, he made similar studies in southern Norway.

His observational and theoretical results are part of the permanent structure of auroral science, though an adequate theory of the aurora is still lacking. Störmer's theoretical studies, being mainly concerned with the motion of a single particle, ignored the essential interactions between the positive and negative charges that must together be involved in the production of auroras. Happily his theoretical studies found an important and unexpected field of application—to cosmic rays. His speculations on radio echoes of long delay, which he associated with a supposed ring current beyond the Moon's orbit, cannot be regarded as established.

He was quick to recognize new auroral features revealed by his photographic syntheses. The most outstanding of these was the remarkable special character of sunlit auroras. He made valuable contributions to auroral spectroscopy, in which field his colleague Vegard was long the chief pioneer. He gave credence to reports of auroral sounds heard by some of his most reliable colleagues. He himself was a born observer, a true naturalist of wide interests. These included botany, the zodiacal light, mother-of-pearl clouds, and meteor trails; to all these subjects he made substantial contributions.

His multitudinous papers were written in Norwegian, Swedish, French, German and English, and were published in many journals and countries. He also wrote a popular work, the content of which ranged from astronomy and astrophysics to atomic physics: it appeared with much success in six languages.

In 1912, after Hale's discoveries of solar magnetism, Störmer visited Pasadena as a research associate of the Carnegie Institution of Washington. This led him to write on solar vortices and the structure of the solar corona. He gave many distinguished lectures on the aurora in foreign countries, for example, at the opening of the Rice Institute, Houston, Texas, in 1918; at the Toronto meeting of the British Association in 1924; and at various British universities in 1930 and 1947. After his Halley Lecture at Oxford in 1947, the honorary degree of D.Sc. was conferred on him; he received a like honour from the Sorbonne. His last long journey was to the auroral conference at London, Ontario, in 1951. In that year he was elected a foreign member of the Royal Society.

In 1955 Stormer published "The Polar Aurora", largely devoted to a valuable connected account of his own observations and theoretical studies on the subject. It is dedicated thus: "To my wife Ada, who never ceased to encourage me to work hard till this book was safely finished". His happy marriage, during more than half a century, was blessed by many children, grandchildren and great-grandchildren.

SYDNEY CHAPMAN

Mr. M. F. W. Holland

THE announcement of the death of Michael Holland in north-west Greenland comes as a shock to many of the younger group now active in the lively borderland between geology, physical geography and glaciology. Brought up in the Pennine hill country near Macclesfield, Holland entered for a time at Birmingham and later at Oxford, where he became a most active member of St. Peter's Hall. A graduate in geography, he was, like many of the post-war generation, strongly attracted to the physical side, and under the direction of Dr. K. S. Sandford proceeded to research and to present his thesis on the geology of north-eastern Spitsbergen, based on the results gained in three summer seasons. In 1956, he organized and led a party to the Sukkertoppen ice cap in west Greenland, some of the results of which are in course of publication. As a consequence of his work there, he was invited to join the International Geophysical Year expedition from Denmark, carrying out glaciological studies on the ice cap of Inglefield Land, under the leadership of Dr. Børge Fristrup. His last letters describe with much verve the active programme of survey and pit studies on which he and a younger Dane, Carsten Velsboe, were engaged at the time of their death, about July 18. On this day the weather maps show an unusually deep depression developing over the region, no doubt accompanied by an exceptional blizzard on the ice cap. It appears likely that in this region the local winds became abnormally strong.

Holland was an extremely fine mountaineer and rock-climber, of wide experience; a natural leader, he had original qualities of mind, perception and elegance. Like Watkins, his energy, organizing ability and unusual capacity as a field-investigator would undoubtedly have brought him to the forefront as an exploratory scientist. His death in the service of international science is indeed a loss, the more so as the conduct of expeditions in the field now demands high standards of technique and scientific accomplishment as well as exploratory hardihood. At the time of his death Holland had several papers in active preparation, and his friends hope to be able to assemble some of his material for publication. As a university teacher his attractive personality and his work as Tutorial Fellow in Bedford College were greatly appreciated.

GORDON MANLEY

NEWS and VIEWS

Soil Microbiology at Rothamsted:

Dr. H. G. Thornton, F.R.S.

DR. H. G. THORNTON, head of the Soil Microbiology Department, Rothamsted Experimental Station, is retiring on September 30. He was educated at Radley and New College, Oxford, and was appointed to the Rothamsted staff in 1919, becoming head of the Bacteriology Department in 1921; he has held his present post since the amalgamation of the Departments of Bacteriology and General Microbiology in 1941. Dr. Thornton has made many notable contributions in soil microbiology, a field which during this period has come to recognition as a distinct subject, and which owes much to his own researches and to his influence upon the large number of microbiologists who have worked at Rothamsted under his direction. Among the earlier investigations in soil microbiology were those on counting techniques, for which Dr. Thornton developed special media and methods and in which he pioneered, in collaboration with R. A. Fisher, the application of modern statistical methods to the elucidation of results. The study of the symbiosis of nodule bacteria and legumes was Dr. Thornton's special interest and has been notably advanced by his work on nodule anatomy and cytology, the concept of strain effectiveness in nitrogen fixation, and on various aspects of nodule origin and development. The results were applied to practical problems of seed inoculation, particularly of lucerne, and prior to 1929 cultures were issued to the farmers direct from his department. Other fields in which Dr. Thornton has worked have been the serology of nodule bacteria and the ecology of soil micro-organisms. He was also concerned in the original work on the selective toxicity and microbial degradation of the phenoxyacetic acids and their derivatives which led to the development of the hormone weed-killers. Dr. Thornton was elected to the Royal Society in 1941 and became foreign secretary of the Society in 1955; he is an active member of a number of scientific societies and national and international committees concerned with microbiology.

Dr. P. S. Nutman

DR. P. S. NUTMAN has been appointed head of the Soil Microbiology Department, Rothamsted Experimental Station, in succession to Dr. H. G. Thornton; he will take up his duties on October 1. Dr. Nutman took his degree in botany at the Imperial College of Science and Technology, London, in 1937, afterwards carrying out research under Prof. F. G. Gregory on the vernalization of cereals. He went to Rothamsted in 1939, and during the War took a leading part in the discovery and early study of the selectively phytotoxic action of 2.4.D (2:4-dichlorophenoxyacetic acid), which resulted in the practical use of this important group of selective weed-killers. In 1953 Nutman was seconded for three years to the Division of Plant Industry, Commonwealth Scientific and Industrial Research Organization, in Canberra, where he set up the new research section on soil microbiology and initiated a number of important lines of work. Nutman's researches at Rothamsted and at Canberra have concerned the formation and functioning of nodules on leguminous plants. He has shown that the number of nodules and their effectiveness in fixing nitrogen are controlled not only by the bacterial strain but also by genetically controlled factors in the host plant, different genes functioning at different and specific stages in the course of nodule development. He has also shown that nodule and lateral root initiation are correlated, and that their origin and growth are affected by inhibitors found in the apices of nodules and lateral roots, and by substances secreted by the roots.

Annals of Physics

One of the most recent additions to the now rather long list of new physics periodicals is the monthly journal, *Annals of Physics* (New York: Academic Press, Inc.), which commenced publication in April and of which the three numbers constituting Vol. 1 (8 dollars; single issues, 3 dollars each) are now available. Vol. 2 will cover the period July–December 1957. Each number contains some five to six original contributions of high standard and on widely different aspects of physics, but almost all so far of a theoretical or mathematical nature. It is the stated intention of the editors, P. M. Morse, B. T. Feld, H. Feshbach and R. Wilson, that the *Annals* shall provide a medium for original work of broad significance, in which the author will be able to give attention to clarity and intelligibility, so that his paper may be read by the widest possible group of readers. It is because they believe that opportunities for presentations of this kind are somewhat limited to-day that the new periodical has been started. It is difficult, however, to distinguish how the various articles in Vol. 1 differ from those to be found in other conventional physics journals, except perhaps that they are occasionally somewhat longer and some may be classed as of semi-review character. The introduction of some papers on purely experimental or technical aspects would help to make the *Annals* more attractive to the general physicist. The format and presentation are excellent. All the contributors to Vol. 1 are members of laboratories in either the United States of America or Canada.

Proceedings of the Physical Society

Since the beginning of 1949 the *Proceedings of the Physical Society* have been published in two sections, Parts *A* and *B*, and these have been available for purchase separately. From time to time the Advisory Committee has altered the distribution of subjects as between *A* and *B*—at one time *A* was mainly devoted to theoretical and *B* to experimental work. However, recently, it has become evident that the maintenance of the distinctive characteristics of the two separate sections was becoming progressively more difficult and that it was inevitable that those who received only one section could not have even specialist interests covered satisfactorily. The Council of the Physical Society has therefore decided to recombine the two sections of the *Proceedings* as from January 1958. It is emphasized that the single issue will contain all the papers that the two separate sections would have contained, and the total content will not be diminished. For convenience of reference and binding, the *Proceedings* will be indexed every six months. The cost to Fellows of the Society for the whole *Proceedings* will be two guineas (£2 11*s*. previously) and to non-members twelve guineas (nine guineas formerly).

Training Overseas Engineers in Britain

More than 150 engineering firms in Great Britain are taking part in the Federation of British Industries Overseas Scholarship Scheme. The scheme provides training with British engineering firms—usually for two years—for selected graduate engineers from the Commonwealth, South and Central America and the Middle East, and is likely to be extended later to include countries in South-East Asia. Its objects are to assist developing countries by increasing their supply of trained engineers and to stimulate the export of British engineering equipment by the spread of British technical knowledge overseas. By March 31, 147 overseas scholars of the Federation from twenty different countries had come to Britain; of these, sixty-five were still here at that date, and eighty-two had returned home after completing their training. Many more awards have been made since then, and the 181st scholar arrived in England recently. Recent arrivals include the first overseas scholars from South Africa and from Jordan. Sir Edward Thompson, chairman of John Thompson, Ltd., Wolverhampton, has succeeded Sir Arthur P. M. Fleming as chairman of the Overseas Scholarships Committee of the Federation of British Industries.

Courses in Higher Technology

The London and Home Counties Regional Advisory Council for Higher Technological Education has prepared a useful bulletin describing special courses in advanced technology which are to be held in the London and home counties region during the next few months. These courses are not connected with those which prepare for examinations and are usually not described in technical college prospectuses. They are generally part-time (usually evening) courses, but full-time courses which are specially arranged and are of not longer than three months duration are also included. The enterprise of most of the colleges concerned is highly commendable. Brighton, for example, has arranged courses dealing with nuclear power stations, jig and tool design, and automatic screw technology; Ealing has a course on transistor technology; Hammersmith has thought of its African and West Indian students by arranging a special course for them dealing with environmental hygiene. Analogue computers form the subject of a course at Hatfield and digital computers one at Hendon; the latter college is to be congratulated for its wide range of courses in management studies. The whole bulletin radiates enthusiasm and enterprise and should be made use of by every managing director and commercial executive in the London area. A similar bulletin describing courses which are to be arranged in the spring and summer of 1958 will be ready in December. Each bulletin costs 3*s*. and may be obtained from the Secretary, Regional Advisory Council, Tavistock House South, Tavistock Square, London, W.C.1.

Coryndon Memorial Museum, Nairobi

THE annual report of the Coryndon Memorial Museum for 1956 (Pp. 28. 1s. Nairobi: Coryndon Memorial Museum) reports the welcome fact that during the year, and especially toward the end of it, the lifting of restrictions on travel from many parts of the reserves to Nairobi made it possible for many more schoolchildren and others to visit the Museum. In fact the total number of visitors for the year was 144,076 compared with 109,011 in 1955 and only 87,662 in 1954. A great deal of work has been accomplished in placing further exhibits on view and improving some of the older habitat groups. Special exhibits, such as one dealing with the life-cycle of the several species of snails which transmit bilharzia, have proved attractive to visitors. Quarters for the African staff of the Museum on a site provided by the City Council have been erected at Makadara.

Preserving Rural England

THE debt owed by the people of England to the Council for the Preservation of Rural England and its branches is unknown to most and immeasurable by all. For thirty-two years those who represent the Council have worked incessantly to see not only that encroachments on the countryside should be done with the least harm to beauty and amenity but also that the standards of all people should be built up to protect and appreciate their heritage. Its success is well known but its task will never be finished. This is well shown in the annual reports of the Central Council and of the Sheffield and Peak District Branch. The Central Council has kept a critical eye on the Service Departments' use of land, on the control of advertisements, electricity undertakings, atomic energy establishments, deviations to existing roads and footpaths, the disturbing growth of petrol filling stations and many other matters, and the Council's vigilance has resulted in the preservation of amenities the proposed removal of which was often unknown to the general public. The work of the Sheffield Branch has helped to prevent a steel rolling mill being established in an attractive hamlet and other disturbances to its lovely green belt. Information may be obtained from the Council for the Preservation of Rural England, 4 Hobart Place, London, S.W.1.

Excavations at Chupicuaro, Guanajuato, Mexico

THE results of the excavation of a large cemetery in an area on the Lerma River, which belongs archæologically to the west, although it has links with the Valley of Mexico, are reported by Muriel Porter (*Trans. Amer. Phil. Soc., Philad.*, 46, 515; 1956). Fine polychrome pottery and peculiar figurines from this area have long been known in museum collections, and the report places them in their context. It is established that the site was occupied continuously through the latter part of the Formative and the beginning of the Classic Periods, from about 500 B.C. to A.D. 400. This is a useful study, which adds materially to our knowledge of an archæologically important but little-known part of Mexico.

Forest Policy in Kenya

A RECENT White Paper entitled "A Forest Policy for Kenya" (White Paper No. 85 of 1957. Pp. 9. Nairobi: Government Printer, 1957) issued by the Colony and Protectorate of Kenya begins with a description of the objects of forest policy, although there has been a forest department in existence in the Colony for more than half a century. The White Paper states that the forest estate of Kenya ranks high as one of the country's most important national assets in its protective aspects of conservation of climate, water and soil, as a source of supply of forest-produce for all uses by the inhabitants and as a revenue earner of high potential. The methods of attaining the objects of the forest policy are explained at length in a recapitulation of what in recent times has often been stated in forestry reports, both in the Dominions and Colonies. It is a welcome reminder that the forests were regarded during the greater part of this century as a mere source of revenue and when this revenue failed in any year recruitment stopped. The total area of Government-reserved forest in Kenya amounts to 2·91 per cent of the land area of the territory. The Government, quite correctly, regards this as a dangerously low proportion, and its policy is to increase it. The first step to achieve success will be to recruit a numerically strong and highly trained staff.

Australites

AUSTRALITES are small pieces of natural glass found scattered over the southern and western half of Australia. They represent an intriguing problem because their origin has never satisfactorily been explained. Although related in chemical composition, physical form, glassy physical state and mode of occurrence to natural glasses found in other parts of the world, it is almost certain that australites are extra-terrestrial in origin; they differ from natural glasses in having symmetrical shapes. Australites have almost the same chemical composition as granites; they differ from stony meteorites in composition in the same way that granites differ from 'basic' rocks. W. A. Cassidy (*Austral. Mus. Mag.*, 12, No. 6) suggests that australites, possessing the typical characteristics of meteorites, were glassy bodies before they entered the Earth's atmosphere and possessed one of the following rotational shapes: oblate spheroid, general ellipsoid, dumb-bell, tear-drop. They were greatly different from the crystalline, irregular-shaped, stony meteorites before they entered the Earth's atmosphere.

Radioactive Carbon Compounds

A FURTHER bibliography, covering the years 1953 and 1954, of syntheses of compounds containing carbon isotopes, has been compiled by J. C. Nevenzel, D. R. Howton, R. F. Riley and G. Steinberg of the University of California (Los Angeles) School of Medicine, and issued as an Atomic Energy Project report (No. U.C.L.A. 395). About 550 additional references to the original literature are given in the report, supplementing those of the original report (U.C.L.A. 316), which covered the literature to 1952, together with a comprehensive formula index of all the compounds mentioned. The commercially available compounds and their suppliers (according to the manufacturers' catalogues) are also given. The report, which can be obtained from the Office of Technical Services, Department of Commerce, Washington 25, D.C., for one dollar, will be useful for those who require isotopically labelled carbon compounds.

Dalton Lecture and Exhibition

THE tenth Dalton Lecture of the Royal Institute of Chemistry, entitled "Coal and Coal Chemicals in the National Economy", will be delivered by Dr. J. Bronowski, director, Coal Research Establishment, National Coal Board, on October 25, at 7 p.m., in the Manchester Town Hall. The chairman will be Prof. R. G. W. Norrish, with the Lord Mayor of Manchester, Alderman Leslie Lever, as principal guest. Admission is by ticket only, obtainable from Dr. R. E. Fairbairn, Imperial Chemical Industries, Ltd. (Dyestuffs Division), Hexagon House, Blackley, Manchester 9.

THE Dalton Exhibition, entitled "Coal and Coal Chemicals in the National Economy", and organized by the Royal Institute of Chemistry, will be held in the Exhibition Hall, Central Library, Manchester, during October 21–26. The opening hours from Monday to Friday are 9 a.m.–8 p.m. and on Saturday 9 a.m.–5 p.m. Admission is free and the Exhibition is open to the general public.

Smoke Abatement Society : Annual Conference

THE twenty-fourth annual conference of the National Smoke Abatement Society will be held in Hastings during October 2–4, under the presidency of Dr. R. Lessing, who will speak on "The Primary Sources of Air Pollution". Speakers include Lord Mills (Minister of Power) and Sir Graham Sutton, who will deliver the eighth Des Voeux Memorial Lecture, on "Air Pollution and the Weather". There will also be discussions on air pollution from road vehicles and on the administration of the Clean Air Act. Further information can be obtained from the Secretary of the Society, Palace Chambers, Bridge Street, London, S.W.1.

Institute of Biology : Parasitology Group

A PARASITOLOGY Group has recently been formed, under the auspices of the Institute of Biology, to provide a forum for the discussion of broad problems in parasitology. A meeting on "The Nature of Immune Responses in Parasitism" is to be held in the rooms of the Royal Entomological Society, 41 Queen's Gate, London, S.W.7, at 2.30 p.m. on October 18. The papers will deal with immune responses to micro-organisms, nematodes and arthropod-borne infections. Further information can be obtained from the secretary of the Parasitology Group, Dr. Elizabeth Canning, Parasitology Department, Imperial College, London, S.W.7.

The Night Sky in October

FULL moon occurs on October 8d. 21h. 42m. U.T., and new moon on October 23d. 04h. 43m. The following conjunctions with the Moon take place: October 26d. 04h., Saturn 1° S.; October 26d. 15h., Venus 6° S. In addition to these conjunctions with the Moon, Venus is in conjunction with Antares on October 17d. 20h., Venus being 2·1° N., Venus with Saturn on October 20d. 12h., Venus being 4·1° S., and Mars with Spica on October 28d. 02h., Mars being 2·9° N. There will be a total eclipse of the Sun on October 23, invisible at Greenwich. Mercury is visible as a morning star during the first week of the month, rising at 4h. 25m. on October 1; superior conjunction is reached on October 24. Venus sets at 18h. 45m., 18h. 30m. and 18h. 20m. at the beginning, middle and end of the month, respectively; during this time its distance from the Earth decreases from 96 to 75 million miles, but its brightness increases more slowly because the visible portion of the apparent disk falls from 0·695 to 0·578. It is a bright object low in the west after sunset. Mars and Jupiter are too close to the Sun for observation. Saturn is visible low in the west after sunset, setting about two hours after the Sun. Its stellar magnitude is + 0·8; it continues to move eastwards in Ophiuchus. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: October 2d. 21h. 27·2m., β Cap. (*D*); October 2d. 22h. 31·6m., β Cap. (*R*); October 3d. 22h. 36·7m., ν Aqr. (*D*); October 16d. 4h. 56·3m., λ Gem. (*D*); October 16d. 5h. 32·8m., λ Gem. (*R*); October 18d. 3h. 36·4m., κ Cnc. (*R*); *R* and *D* refer to reappearance and disappearance, respectively. The Orionid meteors are active during October 15–25; conditions are favourable and the radiant is at R.A. 6h. 24m., Dec. + 15° N.

Announcements

PROF. A. A. MILES, professor of experimental pathology in the University of London and director of the Lister Institute of Preventive Medicine, London, and Prof. C. H. Stuart-Harris, Sir George Franklin professor of medicine in the University of Sheffield, have been appointed members of the Medical Research Council.

DR. M. V. WILKES has been elected first president of the British Computer Society. Dr. Wilkes was a pioneer of the design and construction of automatic electronic digital calculating machines in Britain, and joint author of "Preparation of Programmes for an Electronic Digital Computer" (1951), the first text-book for programmers. In addition to his most recent book, "Automatic Digital Computers", Dr. Wilkes is the author of many papers on computers and their applications, and the computing art owes much to his work as director of the Cambridge University Mathematical Laboratory.

A SYMPOSIUM on "The Newer Metals", arranged jointly by the Royal Institute of Chemistry, the Chemical Society and the Society of Chemical Industry, will be held in the Chemistry Lecture Theatre, University of Manchester, on October 2, commencing at 2.30 p.m. The symposium, which will be arranged in two sessions devoted respectively to beryllium, and to zirconium and niobium, is open to all, but those intending to be present should notify Dr. R. E. Fairbairn, I.C.I. (Dyestuffs Division), Hexagon House, Blackley, Manchester 9.

A CONFERENCE organized by Aslib, intended to bring together those most concerned in formulating policies for the technical college libraries of the future and representatives of industry, will be held in the Connaught Rooms, Great Queen Street, London, W.C.2, on October 30. During the morning session, under the chairmanship of Alderman J. W. Brown, Sir Edward Boyle will give the opening address, the Earl of Verulam will speak on "Libraries: a Liberal Element in Technical Education", and S. T. Broad on "A Technical Library Service". In the afternoon the chairman will be Sir Wavell Wakefield and the lectures are on "The Technical College Library as an Educational Instrument" by Dr. J. Topping and "Co-operation with Local Industry" by P. P. Love. Further information can be obtained from Aslib, 4 Palace Gate, London, W.8.

SCIENTISTS IN THE GOVERNMENT SERVICE IN BRITAIN

SPECIAL PROMOTIONS

FURTHER special posts have been created in the Civil Service under provisions included in the White Paper on the Scientific Civil Service (Cmnd. 6679 : 1945) to provide for the promotion of individual research workers of exceptional merit. They include the following :

Deputy Chief Scientific Officers

Dr. W. M. Evans. Following a short period in university teaching, Dr. Evans joined the Armament Research Establishment in 1937, and moved during 1950–54 to the Atomic Weapons Research Establishment. He returned to the Ministry of Supply in 1955 to take up his present post as a principal superintendent at the Armament Research and Development Establishment. He obtained the degree of D.Sc. in 1953. In his early years in the Armament Research and Development Establishment Dr. Evans worked on detonation problems, making many contributions to the study of shaped charges, the mechanism of jet formation, penetration of armour and the effects of stress pulses. Since returning to the Establishment he has had charge of a Division covering all aspects of detonating munitions. Dr. Evans, whose work is distinguished by a combination of outstanding experimental technique and depth of physical insight, enjoys a high reputation both in Britain and abroad.

Dr. D. W. Holder. Dr. Holder joined the Aerodynamics Division of the National Physical Laboratory in 1944. He leads a team working on problems of high-speed flow, and has personally made many important advances in aerodynamics. The work which he and his group have done on shock-wave boundary layer interaction and on boundary layers in transonic flow are particularly well known. Dr. Holder is an authority on high-speed tunnel design and has taken a leading part in planning the new facilities at the National Physical Laboratory for research at supersonic and hypersonic speeds.

Mr. J. S. Thompson. Mr. Thompson joined the Royal Aircraft Establishment at the outbreak of war in 1939. Previously he had worked on steam turbines, making pioneer experimental studies of the high-speed flow of steam in nozzles and of secondary flow in cascades. At the Royal Aircraft Establishment he has become intimately connected with the high-speed wind tunnel. His work has combined brilliance in experiment with a deep insight into the theoretical background ; it contributed greatly to the high quality of the scientific output of the tunnel during and after the Second World War, and it established his reputation as an authority on experimental work at high subsonic speeds. He moved to Bedford in 1947 and became responsible for designing the 8-ft. supersonic tunnel and the 4 ft. × 3 ft. high supersonic speed wind tunnel. These two tunnels together represent an investment of more than £10,000,000 and the combined power is up to 150,000 h.p. His many personal contributions and balanced judgment have been invaluable in instrumentation, test techniques and model production problems, and the bringing of the 8-ft. tunnel into successful operation represents an outstanding achievement.

Senior Principal Scientific Officer

Mr. R. B. Benson. Mr. Benson, of the Department of Entomology of the British Museum (Natural History), joined the Museum staff in 1929, and his career has been devoted to the study of sawflies (Hymenoptera-Symphyta), on which he is an internationally recognized authority. He was recently awarded a Leverhulme Fellowship to study sawflies in Canada and the United States.

Dr. K. D. Froome. Dr. Froome, who joined the National Physical Laboratory in 1949 and is now officer-in-charge of the interferometry section of the Metrology Division, is well known for his precise work on microwave measurements.

Dr. R. Jones. Dr. Jones, after joining the Road Research Laboratory in 1939, was engaged on war-time problems. He has been promoted for his work on ultrasonic methods for the non-destructive testing of materials.

Dr. K. W. Mangler. For the past ten years Dr. Mangler has been employed in the Aerodynamics Department at the Royal Aircraft Establishment, where he is at present working on the fluid dynamics problems of the hypersonic regime.

Mr. L. Permutter. Mr. Permutter is employed at the Armament Research and Development Establishment, where he works on the problems of the gun/shot combination, including internal, external and terminal ballistic performance.

Dr. A. W. H. Pryde. Dr. Pryde works at the Explosives Research and Development Establishment where, among other things, he has contributed to all the development work on new and improved methods for manufacturing picrite and devised a new continuous process for the nitration of toluene to T.N.T.

Dr. O. Simpson. Dr. Simpson is a research physicist at the Services Electronics Research Laboratory, Baldock. During the past few years he has been investigating the electronic properties of aromatic hydrocarbons with particular attention to electrical conductivity, fluorescence, photo-effects and the migration of excitation energy. The results obtained with this new class of semiconducting compounds have proved most interesting and encouraging, and an extension of the research to intermetallic compounds of the Group III–Group IV variety is in view.

Dr. D. J. Thomas. Dr. Thomas, who has been employed at the Chemical Defence Experimental Establishment since 1937, is distinguished for his research and development work on particulate filters and filtration ; lately his work has taken on additional importance in relation to atomic energy laboratories and production plants.

Similar promotions have been made by the United Kingdom Atomic Energy Authority, as follows :

Deputy Chief Scientific Officer

Mr. T. H. R. Skyrme. Mr. Skyrme has been leader of the Nuclear Physics Group of the Theoretical Physics Division at Harwell since 1950. Mr. Skyrme graduated in Cambridge in 1943 and joined the Los Alamos Laboratory as a member of the British Mission in 1944. He became a research fellow in the Department of Mathematical Physics, University of Birmingham, in 1946, after which he returned to the United States to spend two years at the Massachusetts Institute of Technology and at the Institute for Advanced Studies at Princeton. During the past seven years at Harwell he has published a number of important papers on quantum field theory and nuclear structure.

Senior Principal Scientific Officer

Dr. P. A. Egelstaff. Dr. Egelstaff, who joined the Atomic Energy Research Establishment in 1947 and has specialized in neutron physics, is now head of the Pile Neutron Research Group.

Dr. A. R. Fraser. Dr. Fraser is a group leader in the Theoretical Physics Division of the Atomic Weapons Research Establishment, where he has done distinguished work in eliciting the interaction of radiation with hydrodynamic flows. Here the local absorption of energy depends upon density and temperature and so reacts on, and is itself conditioned by, the hydrodynamics of the field.

Dr. J. H. O. Varley. Dr. Varley is a member of the Metallurgy Division of the Atomic Energy Research Establishment and has been particularly concerned with work on the theory of alloy formation, the volume thermal expansion of solids and radiation damage in solids. He is now in charge of work on corrosion phenomena and surface reactions.

The Agricultural Research Council is also making a promotion to the rank of senior principal scientific officer :

Dr. Helen K. Porter. Dr. Porter, a member of the staff of the Research Institute of Plant Physiology at the Imperial College of Science and Technology, London, is studying the mechanisms of sucrose synthesis in the germinating embryo of the cereal plant, and of starch synthesis and degradation in the leaf.

TECHNICAL SCHOOLS IN PRAGUE

250th ANNIVERSARY

CZECHOSLOVAKIA has an ancient tradition not only in arts and humanities, but in technical sciences as well. A technical school was founded in Prague 250 years ago. This school, it is claimed, was the first public technical school in Europe. Its founder and first teacher was Joseph Willenberg, a native of Silesia. He, like many young men at that time, had gone to France to obtain knowledge of military engineering through service in the army. When, however, Louis XIV declared war on Austria owing to the dispute over the Spanish Succession, Willenberg, not wishing to fight against his native country, left France. In Austria he tutored young noblemen in the art of fortification and accompanied them in campaigns. After 1703 he settled in Prague, and from there he addressed a petition to the Emperor Leopold I, requesting permission to open a public school of engineering where, upon payment of a fee, six higher and four lower noblemen and two bourgeois youths would be instructed in the art of engineering. The request was granted by Emperor Joseph I, the son of Leopold, but the Bohemian States were unable to open the school at once as, at that time, the Bohemian provinces were utterly exhausted by taxation and conscriptions. Consequently, Willenberg undertook various engineering jobs, executing plans and designs for the fortification of Pilsen and other towns. Ultimately he applied direct to the Emperor Charles VI, the son of Joseph I. The Emperor then ordered the States speedily to do what they had been ordered in 1707, and the desired school, the Czech Professional Engineering Institute, was established by the States in 1717. Willenberg commenced regular instruction in his private apartment in the following year, with an annual attendance of twenty-four pupils. The school, then called Česká stavovská inženýrská škola (the Czech States Engineering School), was converted about a hundred years later into a polytechnic, the principal of which was F. J. Gerstner, who suggested the construction of the first horse-drawn railway on the European Continent.

In the course of the following years the school developed successfully, and produced a number of accomplished experts who made eminent contributions to the advancement of the Czech countries, and whose work was widely recognized abroad. After many changes in its organization, in harmony with the development of the technical sciences and the growing need for qualified technologists, the Prague technical school reached its present form. As the Technical University of Prague, it represents a whole complex of specialized faculties where thousands of undergraduates receive instruction.

Naturally, the Czechs are proud of their endeavours in technical education, and recently celebrated the 250th anniversary of the foundation of technical schools in Prague. Invitations were sent to universities and colleges all over the world and 135 foreign scientists took part in the celebrations. They came from twenty-three countries, including Albania, Austria, Bulgaria, Chile, China, Egypt, Finland, France, Great Britain, Germany (West and East), Hungary, India, Iran, Iceland, Italy, Korea, Poland, Rumania, Switzerland, the United States and the U.S.S.R. There were two representatives from Britain, Mr. D. S. Cardwell, vice-principal of the Manchester College of Science and Technology, and Prof. J. S. Rankin, of the Royal College of Science and Technology, Glasgow.

The inaugural proceedings of the celebrations on May 27 were held in the Vladislav Hall of Prague Castle. In an ante-room rectors and professors were arranged in pairs in alphabetical order of country. The two British representatives had the honour of leading in the procession behind the two chancellors of the Universities of Prague. The vast hall is in the oldest existing building of Prague Castle, and is an outstanding memorial to Czechoslovakian medieval architecture. It was filled to overflowing by an audience who were obviously keenly interested in all that took place. When the academic body was properly arranged on either side of the huge platform, the President of the Republic and members of the Government walked in and occupied an imposing position in the gallery of the platform. During the whole of the proceedings and even during the Rector's dignified address, bulbs flashed and cameras clicked and high-powered lamps illuminated the platform party while films were being made. It was all very impressive; the organization was good, and one sensed an atmosphere of academic dignity.

On the same day we were transported to the Auditorium Maximum of the Carolinum, a renovated hall of the Charles University of the fourteenth century. An honorary degree of doctor of technical science was awarded to Prof. D. Blochincev, director of the United Research Institute of Nuclear Physics. Owing to illness, a similar award could not be conferred on Dr. M. Roš, director of the Federal Research Institute for Testing and Research in Industry, Zurich.

Another important part of the celebrations was the international scientific conference in the Assembly Hall of the Congress Palace. It lasted for three days, with morning and afternoon sessions. To begin with, each foreign delegate was called to a microphone in the centre of a large platform and conveyed his congratulations and felicitations to the rector and staff of the Technical University of Prague. At the same time, scrolls and appropriate presents were ceremoniously handed over to the chairman of the meeting. The hall could seat approximately 2,000 people, yet each one could listen in to all the speeches in one of the official languages—Czech, Russian, English, German and French. Apparently there were interpreters for other languages like Chinese, Korean and Arabic. At the conference eighty-five scientific papers were read, thirty-nine of which were by foreign scientists interested in the branches dealt with at the Technical University of Prague, namely, constructional building, architecture and civil engineering, mechanical engineering, electrotechnics, sylviculture, geodesy and engineering economics.

Everything possible was done to make the visit of each foreign guest pleasant and profitable. For example, each day a car with chauffeur was put at the disposal of Mr. Cardwell and Prof. Rankin, to transport them to any factory or place of interest within a day's journey of Prague. Both spent a pleasant day at Karlsbad, and lunched in the palatial Moscow Hotel, which would be difficult to surpass anywhere in food and furnishings. In all visits a young engineering lecturer, good-natured, intelligent and modest, acted as interpreter. One met many men of this type, and the material progress of their country should be bright if they are given the proper encouragement and incentives.

The university engineering laboratories were well equipped, and much useful research has been done. The education of technologists is being pursued with vigour, and from the figures supplied it would appear that the Czechs are producing at least twice as many highly qualified technologists per million of population as Britain. The various technological courses seem to be somewhat longer than in a British university or college, and the standard attained in each subject is quite high.

Bus tours were also arranged to take the delegates to various industrial centres, such as the Tesla Works at Vrchlabi, where a large proportion of the workers are women who were undoubtedly highly proficient.

Many social evenings were arranged. A visit to the opera, and two receptions at which music and dancing were indulged in, were much appreciated by all the delegates. One had the opportunity of making friendly personal connexions, especially with the rectors, professors and lecturers of the Universities of Prague.

I shall always remember the kindliness and friendliness of the Czechs I met, and will watch the future development of their country with understanding, sympathy and good wishes.

J. S. Rankin

NON-SPECIFIC IMMUNITY

During the spring meeting of the British Society for Immunology, which was held during May 10 and 11 at the Westminster Medical School, an afternoon was devoted to a symposium on "Non-specific Immunity", with Prof. A. A. Miles (Lister Institute) in the chair.

Prof. Miles attempted to define the rather vague field of non-specific immunity, and concluded that the term was largely, though not wholly, synonymous with effective defences against pathogenic parasites that were not mediated by the specific action of antibodies or presumed antibodies. In the analysis of non-specific immunity, it was essential, not only to identify various single factors—cellular or humoral—that might contribute to immunity, but also to relate them to the constitutive and adaptive defence mechanisms of the metazoan host as a whole. It is probable that the non-specific immunity in different anatomical sites of infection and in different cellular and humoral systems of the body can to some extent vary independently in the infected animal.

Dr. G. Biozzi (Paris) described investigations of the phagocytic functions of the reticulo-endothelial system carried out in collaboration with B. N. Halpern, B. Benacerraf and C. Stiffel. The rate of blood clearance of carbon particles injected intravenously was used for measuring the total phagocytic function of the reticulo-endothelial cells of the blood vessels, involving mainly the liver and spleen, which together accounted for 90 per cent of the phagocytic activity. During infection with *Salmonellae* or tubercle bacilli there was an increase in the phagocytic activity which lasted throughout the period of infection. In severe infections attended by death, the initial hyper-reactivity was followed by a rapid drop when the defences were overwhelmed. The substance found responsible for the variations in phagocytic function during infection with Gram-negative organisms was the lipopolysaccharide endotoxin. Overstimulation before the infection allowed the recovery of 80 per cent of rats injected with a dose of *Salmonella* organisms 100 per cent lethal for controls.

Dr. C. H. Lack (Royal National Orthopædic Hospital) described the role of non-specific factors affecting susceptibility to tuberculosis. Leucocytes could inhibit tubercle bacilli by release of lysozyme or by the production of lactic acid. On the contrary, most keto-acids and polycarboxylic acids favoured mycobacterial growth. Another important factor was oxygen, and pathogenic strains distinguish themselves by their ability for survival at low oxygen tensions. In the human lung most infections resulted in the embedding of bacilli in solid caseous foci in which they rapidly decreased. Rapid bacillary multiplication followed softening of caseum, presumably due to increased availability of oxygen, and possibly to the release of nutrients by proteolysis. It is the softening of caseum that is usually responsible for tuberculous disease as distinct from infection. Solid caseation followed by softening was not found in the hyperimmune animal injected with bacilli in adjuvant. Dr. Lack has shown that human plasmin can digest human caseum. The increased morbidity of females between 15 and 35 years could possibly be related to enhanced plasmin activity at the pre-menstrual period. Abnormal plasmin activation may also be the mechanism of the rapid cavitation following severe psychical trauma. The study of the factors of such mechanisms was the most fruitful approach to the problem of human tuberculosis.

Dr. E. Suter (University of Florida) described the effect of phagocytosis on the respiration of micro-organisms. The important contribution of the phagocytic system to natural resistance can be mediated through either bactericidal substances (for example, phagocytin and leukin), or through subtle influences upon bacterial metabolism and on enzymatic breakdown of bacterial components. Using organisms labelled with carbon-14, the fate of bacillary carbon can be followed in the intracellular environment. Tubercle bacilli maintained their respiratory-rate within phagocytes. Furthermore, little or no bacillary carbon was handled by phagocytic enzymes and appeared in the respiratory carbon dioxide. This metabolic resistance of tubercle bacilli to the phagocytic environment seemed to depend upon their structural intactness. Thus sonic vibration of bacilli or the presence of non-ionic detergents altered this relationship to the advantage of the cell. The findings were quite different when organisms were phagocytosed which were less resistant to intra-cellular environment, such as *Mycobacterium phlei*, *Bacillus subtilis*, *Staphylococcus albus* and *aureus*, and *Streptococcus pneumoniae*. Their metabolic activity was reduced within one or two hours to one-tenth or one-hundredth of their original activity, and bacillary carbon appeared very quickly in the respiratory carbon dioxide of the phagocytes.

Dr. D. Rowley (St. Mary's Hospital) described the work of J. G. Howard, A. C. Wardlaw and himself which derived from the observation, some years ago, that injection into mice of small quantities of cell walls of Gram-negative bacteria produced rapidly developing immunity to subsequent infections by other Gram-negative organisms. This non-specific immunity was of short duration (up to 14 days) and was not accompanied by any significant changes in the level of complement or natural antibody. Lipopolysaccharide from cell walls produced this immunity in doses as small as 1 μgm. per mouse, and more recently the lipid *A* fraction of this has been found highly active. Although injected lipopolysaccharide rapidly increased the serum properdin, it is unlikely that this accounted for the immunity, for this extended to organisms not affected by the serum bactericidal activity of properdin and complement. The intravenous injection of lipopolysaccharide labelled with phosphorus-32 resulted in the rapid removal of most of this by the reticulo-endothelial system. Using the rate of removal of this labelled material as a test of function of the reticulo-endothelial system, it was shown that increased phagocytic activity accompanied the development of immunity.

Dr. D. G. Evans (Medical Research Council, Hampstead) discussed the immunity produced in mice by intraperitoneal injection of pertussis vaccine against the intracerebral challenge of living virulent organisms. The steep immune response without lag was unlike that associated with antibody production, and occurred before circulating specific antibodies were detectable. This early immunity was transient and declined at 10–14 days, to be followed by the slower development of a true antibody type of immunity, which reached maximum at 28 days. The early and later immunity were associated with a common factor so that vaccines with a good early response also elicited a good later response. The purified pertussis antigen of Pillemer produced both responses. The production of early immunity by pertussis vaccine was non-specific, for Dubos has shown that marked protection detectable within a few hours was produced in mice against staphylococcus and tubercle bacilli. This early immunity is probably not due to an increase in properdin, for it has been shown that mice given properdin at the time of challenge were no more resistant than normal mice.

STEROIDS IN PHARMACY AND MEDICINE

The chairman's address to the British Pharmaceutical Congress held at Bristol during September 2–6 was given by Mr. Frank Hartley. In it, he surveyed the broad field of the steroids, beginning with the earliest known members of the group, the sterols, and ending with some of the latest researches on anabolic steroids.

He referred briefly to cholesterol, the bile acids and antirachitic vitamins, mentioning some of their significance for pharmacy. He then directed his attention to the steroid hormones, dealing in turn with œstrogens, progestational substances, adrenocortical hormones, steroids as anæsthetics, androgens and anabolic agents. It is difficult to select, from this masterful survey, a few topics for special comment, and what follows must necessarily reflect my particular interest.

Mr. Hartley discussed some of the recent developments in the search for clinically useful steroids among the progestational substances, adrenocortical hormones, androgens and anabolic substances. The 19-nor-steroids came in for a good deal of attention under several of these headings. 19-Nor-progesterone is more active than progesterone, as is 19-norethisterone than ethisterone. 17α-Methyl-19-nortestosterone (methylœstrenolone) is among the more potent of the new oral progestational substances; other derivatives, such as 17α-ethyl-19-nortestosterone (norethandrolone) and 17α-ethynyl-5(10)-œstrenolone, also exhibit progestational activity. Some of these compounds have marked anabolic properties as well.

Mr. Hartley mentioned the Δ^1 derivatives of cortisone and hydrocortisone, the now well-known substances prednisone and prednisolone, and then discussed still more recent developments. An unsaturated linkage between C_6 and C_7 converts prednisone and prednisolone into even more potent glucocorticoids. Halogenation at C_9 and methylation at C_6 have yielded 9α-fluoro-6α-methylprednisolone, which is stated to have a glucocorticoid activity some two hundred times that of hydrocortisone. 9α-Fluorohydrocortisone is now well known for its potent mineralocorticoid activity. Mr. Hartley referred to numerous other derivatives which have been produced by the steroid chemists, including steroids with additional hydroxyl groups at carbons 2, 6, 12, 14 and 16. The potential value of these remains to be explored. The 19-nor analogues of cortisone and hydrocortisone are less potent than the parent substances.

Mention has already been made of studies on 19-nortestosterone and its derivatives as anabolic agents; esterification with benzoic, *cyclo*pentylpropionic or phenylpropionic acids prolongs their effectiveness by intramuscular injection. Recent work has shown that 4-chlorination or 6-methylation of testosterone derivatives increases their anabolic/androgenic ratio. The androgenic activity of 11β : 17β-dihydroxy-9α-fluoro-17α-methylandrost-4-en-3-one (fluoxymestrone) is stated to be ten times greater than that of methyltestosterone, but in spite of the presence of the 11-hydroxy group, it is said not to give rise to oedema or to hypertension.

In concluding, Mr. Hartley pointed out that every natural steroid hormone possesses not one but a whole range of biological activities, some of them unnecessary or even undesirable in their application therapeutically. Consequently, the need has arisen for steroids 'tailored' to a particular therapeutic requirement. Progress towards meeting this need has been mentioned above. Some of the substances thus artificially created are often many times more active than the natural substances they replace. For the future, Mr. Hartley felt that the most important application of steroids would be in the field of gerontology, neuroendocrinology and population control. This progress will be achieved by the continued close collaboration of steroid chemists, biologists, pharmacists and clinicians. G. I. M. SWYER

RADIO RESEARCH 1956

THE annual reports of the chairman of the Radio Research Board and of the director of radio research are contained in the publication "Radio Research 1956"*. With the completion and occupation of the new buildings at the Radio Research Station, Slough, in the late summer of 1956 (see *Nature*, 180, 163; 1957), the final transfer of the former Radio Division of the National Physical Laboratory at Teddington to Slough has now been completed. In addition to the work at the main Station at Slough, ionospheric observatories have continued to be maintained at Inverness, Port Stanley and Singapore, and further work is carried out under contract with the Department at the Universities of Cambridge, London and Wales. An ionospheric station has also been equipped and staffed at the Royal Society base at Halley Bay, Antarctica, in connexion with the International Geophysical Year.

The main emphasis of the research programme has been concerned with ionospheric and tropospheric radio-wave propagation over a very wide frequency band. The efficient forecasting of ionospheric transmission conditions is an important practical task, which has continued to be the concern of the Department. In addition to the routine ionospheric recordings made at the Department's observatories, studies of long-distance communications in the high-frequency band (17–24 Mc./s.) have been made on fixed frequencies, using signals from distant pulse transmitters. A variable-frequency sounding apparatus, which operates in increments of 10 kc./s. every 0·4 sec. in the frequency band 5·5–25 Mc./s., has also been constructed for studying long-distance propagation and given preliminary trials. Another aid to this study, which is now being pursued from the practical point of view, is the technique of back-scatter sounding. In this, conditions for transmission over long distances are investigated by a radar method in which the signals are returned by back-scatter at the ground, obviating the need for a distant transmitter. Good results have been obtained, and an operational equipment has now been built for routine use.

The study of forward-scatter in the ionosphere (*E*-region) of signals in the very-high-frequency band (> 30 Mc./s.) has continued. Measurements of both the amplitude and the angular spread and direction of arrival of the scattered energy have been made in an attempt to elucidate the mechanism responsible. Definite conclusions are not yet possible, but it appears that the night-time signals are more likely to arise from weak reflexions from a large number of trails of ionization produced by low-magnitude meteors, rather than from scattering from turbulent irregularities in the ionosphere. In this work, strong steady signals are frequently received in the summer, due to direct reflexions from sporadic *E*-ionization. Investigations of the forward-scatter in the troposphere of very-high and ultra-high-frequencies have also been started at Slough, in collaboration with the Post Office. Experiments on a frequency of 1,370 Mc./s. received over a path of 150 km. are in progress, with the object of elucidating the propagation process and developing practical communication links based on the phenomenon. The study of the statistical correlation between certain meteorological features and field-strength measurements beyond the horizon of the transmitter has continued, as have also the effects of radio noise due to atmospherics on radio communications.

The possibilities of using very low frequencies (10–20 kc./s.) for long-distance navigational aids are being investigated in co-operation with the Admiralty. It is intended to develop a system which functions on the phase-difference between signals received from two or more widely separated phase-locked transmitters, and preliminary investigations of the variable phase changes introduced by the ionosphere are in progress.

Apart from a summary of the many studies of radio wave propagation undertaken by the Department, "Radio Research 1956" includes a brief description of some of the work sponsored at universities, and of theoretical work on the characteristics of the ionosphere. A particular aspect of the latter is a study of the effect of solar eclipses on the ionosphere, which yields information on the brightness of the Sun's disk and on the physical properties of the ionized layers. Work has also continued on the development of power-measuring standards for continuous-wave and noise powers in the cm. waveband. Another aspect of work of the Department which is described is a study of semi-conductors and ferrites. Silicon is assuming an increasingly important role in the development of transistors, and particular attention has been paid to operation at high frequencies (up to 100 Mc./s.).

---

* Department of Scientific and Industrial Research. Radio Research 1956: The Report of the Radio Research Board and the Report of the Director of Radio Research. Pp. iv+47+4 plates. 3s. net. (London: H.M. Stationery Office.)

"Radio Research 1956" is thus a brief survey of the investigations for which the Radio Research Station has been responsible during the year. A complete list of papers on its work published in scientific journals during 1956 is given as an appendix to the report. GEOFFREY M. BROWN

THIOLS, DISULPHIDES AND THIOSULPHATES: SOME NEW REACTIONS AND POSSIBILITIES IN PEPTIDE AND PROTEIN CHEMISTRY

By DR. J. M. SWAN

Biochemistry Unit, Commonwealth Scientific and Industrial Research Organization, Wool Textile Research Laboratories, Melbourne

THIS communication is concerned with the conversion of thiols and disulphides to organic thiosulphates, and with various reactions of the thiosulphate group, both in simple compounds and in proteins. A recent method for the specific and symmetrical fission of disulphide bonds has led to a new process for dissolving keratins, and to a method for tagging proteins reversibly with radiosulphur. Convenient syntheses of mixed disulphides, especially unsymmetrical cystine peptides and peptide intermediates, a simple method for studying thiols and disulphides on paper chromatograms, and reactions which may lead to the specific fission of peptide chains at cystine or cysteine residues are also described.

Cystine is known to react reversibly with aqueous sulphite to give cysteine and an equimolar amount of 'cysteine S-sulphonic acid' (β-amino-β-carboxyethyl thiosulphate) (reaction 1; $R = HO_2CCH(NH_2)CH_2$—). The latter compound is more conveniently termed S-sulphocysteine, since this allows the corresponding residue to be easily named in a peptide sequence. This reaction seems to be general for water-soluble disulphides, although the point of equilibrium may be very different in different cases[1-3].

$$RSSR + SO_3^{2-} \rightleftharpoons RS^- + RSSO_3^- \quad (1)$$

Kolthoff and Stricks[4] have shown that trace amounts of cystine and cysteine can be estimated in alkaline solution by amperometric titration with cupric ions in the presence of sulphite. The cupric ions are reduced to cuprous, and the sole product from both cysteine and cystine is S-sulphocysteine:

$$RSSR + 2Cu^{2+} + 2SO_3^{2-} \rightarrow 2RSSO_3^- + 2Cu^+ \quad (2)$$

$$RSH + 2Cu^{2+} + SO_3^{2-} \rightarrow RSSO_3^- + 2Cu^+ + H^+ \quad (3)$$

Both reactions go to completion rapidly and offer a number of possibilities in preparative chemistry and in the study of peptides and proteins containing cysteine or cystine.

Extraction of keratin derivatives. The cystine disulphide bonds in wool are broken symmetrically by reaction with cupric-ammonium-sulphite (reaction 2). A typical example is as follows: when 1 gm. of merino 64's wool is treated overnight at room temperature with 200 ml. of a solution which is 0·02 M in cupric ammonium hydroxide, 0·05 M in sodium sulphite and contains also 8 M urea to swell the wool and assist penetration of the other reagents (pH of solution 9·8–10·5), about 75 per cent of the wool substance is dissolved. With a reaction time of 2–6 days, 85–90 per cent of the wool can be dissolved. The reagent will also dissolve chicken feathers and powdered horn to the extent of 95 per cent and 85 per cent, respectively. The protein ('S-sulphokerateine') can be precipitated from the extracts by acidification and dilution, or by addition of ammonium sulphate. It may be freed from copper without precipitation by dialysis against citrate or ethylenediaminetetraacetate at pH 7–9. The protein derivative is soluble down to pH 5, and further study of this material is in progress. Urea may be omitted from the cupric-ammonium-sulphite reagent; extraction of the protein is then slower, but 70–90 per cent can be brought into solution over a period of about six days. The ammonia may be replaced by ethylenediamine, and the extraction process can be carried out at + 2°. The thiol-rich protein ('kerateine') obtained from wool by extraction with alkaline thioglycollate[5] is rapidly transformed by cupric-ammonium-sulphite (reaction 2) to an S-sulphokerateine similar to the protein obtained directly from wool as described above.

Labelling proteins with sulphur-35. If sulphite containing sulphur-35 be used in the above reactions, the protein acquires a radioactive label in the thiosulphate group. In addition to the obvious usefulness of such a label, for example, in following fractionation procedures, the reaction should provide an extremely sensitive test for the presence of thiol or disulphide in a protein or other compound. In order to study the stability of the protein thiosulphate radical, S-sulphokerateine containing sulphur-35 was first dialysed for ten days at 2° against 0·1 N potassium hydrogen carbonate, pH 7·9, until the radioactive material dialysing during each 24 hr. amounted to only 0·08 per cent of the total. Aliquots of this solution were then dialysed for 40 hr. at 2° against various reagents. Over the pH range 1–9, the measured decomposition was quite small (0·9–3·2 per cent), rising to 7·3 per cent at pH 10·9 and very sharply to 96 per cent in 0·1 N sodium hydroxide. In 1 N and 6 N hydrochloric acid under the same conditions, the decomposition was 1·8 and 6·0 per cent, respectively.

Thiosulphates are known to react readily with aqueous cyanide to give thiocyanates and sulphite ion (reaction 4)[6], while alkyl thiosulphates marked with sulphur-35 in the $—SO_3H$ portion are known to undergo exchange with sulphite ions according to reaction 5[7]:

$$RSSO_3^- + CN^- \rightarrow RSCN + SO_3^{2-} \qquad (4)$$

$$RSS^*O_3^- + SO_3^{2-} \rightleftharpoons RSSO_3^- + S^*O_3^{2-} \qquad (5)$$

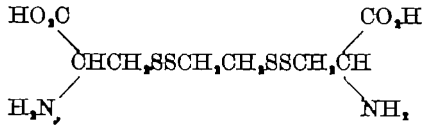
Both reactions have been established for S-sulphokerateine. Dialysis against cyanide at pH 9·6, or against sulphite at pH 8·6, leads to almost complete loss of radioactivity from the protein. Since reaction 1 is reversible, it can be predicted that thiosulphates will be converted by excess of a (different) thiol to the alkyl thiol corresponding to the thiosulphate used (reaction 6):

$$RSSO_3H + R'SH \rightleftharpoons H_2SO_3 + RSSR' \xrightarrow[R'SH]{\text{excess}} RSH + R'SSR' \qquad (6)$$

This reaction has also been demonstrated, both for S-sulphokerateine and for simple alkyl thiosulphates, using thiols such as benzyl mercaptan, thioglycollic acid, etc. Sodium amalgam, stannous chloride, sodium stannite, sodium arsenite and sodium hyposulphite (dithionite) are also effective reducing agents. Formation of the thiosulphate suggests itself, therefore, as a convenient method for stabilizing a sensitive thiol, with the possibility of returning at will to the original thiol. Thiosulphates may also be converted to thiol by hydrolysis in hot dilute acid[1].

Specificity of the reaction. A paper chromatographic investigation has shown that all the common amino-acids, as well as glutamine, asparagine, lanthionine, lanthionine SS-dioxide, methionine SS-dioxide and 3,5-dibromotyrosine, and a range of dipeptides, are all unaffected by the cupric-sulphite reagent. On the other hand, cysteine, cystine, glutathione and various cystine peptides all gave new ninhydrin-positive spots corresponding with conversion to the thiosulphate. This reaction can be effected on the paper simply by treating the dried amino-acid or peptide spot with dilute sodium sulphite solution. Copper is not necessary since the thiol formed is quickly reoxidized by air. Unsymmetrical cystine peptides yield two thiosulphate derivatives corresponding to the residues on each side of the disulphide bond. The thiosulphates have R_F values close to those of the corresponding sulphonic acids. Since the cupric–sulphite reaction is so specific, it suggests itself as an alternative to oxidation with peracids for obtaining linear peptides from complex cystine-containing proteins such as insulin and lysozyme, especially as oxidation by peracids destroys tryptophan residues and may result in partial destruction of lysine and arginine residues[8] and modification of tyrosine residues[8]. It has been shown that insulin does, in fact, react rapidly and quantitatively with the cupric-sulphite reagent in 0·05 M ammonium hydroxide with separation of the two peptide chains.

Synthesis of mixed disulphides. Reaction 6 shows that if a thiosulphate be brought into reaction with one equivalent of a (different) thiol, the equilibrium mixture should contain the unsymmetrical disulphide. Footner and Smiles[9] examined the reaction of various thiosulphates and thiols in alkaline solution, but only in one case was the mixed disulphide obtained. In their other examples, the insoluble product consisted of a mixture of the two symmetrical disulphides, which presumably arise from the mixed disulphide by a process of rearrangement. In the cases studied, the reaction was driven to completion by the insolubility of the products formed. It is known that disulphide rearrangement is catalysed in alkaline solution by traces of thiol, but that rearrangement is minimized in dilute acid solution, where thiols in fact inhibit rearrangement[10]. Accordingly, the thiosulphate–thiol reaction has been re-examined in dilute acid solution, a stream of nitrogen being passed through the mixture to remove the sulphur dioxide formed. Under these conditions, mixed disulphides have been obtained in high yield. Successful syntheses have also been carried out in alkaline solution in the presence of strontium ions; the reaction is then driven to completion by the precipitation of sulphite as strontium sulphite. S-sulpho-L-cysteine reacts with benzyl mercaptan, thioglycollic acid and N-carbobenzoxy-L-cysteine to yield in each case the respective mixed disulphide; the same products are also obtained from L-cysteine using benzyl thiosulphate, carboxymethyl thiosulphate and N-carbobenzoxy-S-sulpho-L-cysteine, respectively. S-sulpho-L-cysteine also reacts with L-cysteine to give L-cystine having full optical activity. Glutathione reacts with S-sulpho-L-cysteine at pH 5 in a stream of nitrogen to give the mixed disulphide of cysteine and glutathione; in this case, partial rearrangement also occurs to cystine and oxidized glutathione. Cysteine reacts with disodium ethylene dithiosulphate to give a new amino-acid (I) containing two disulphide bonds.



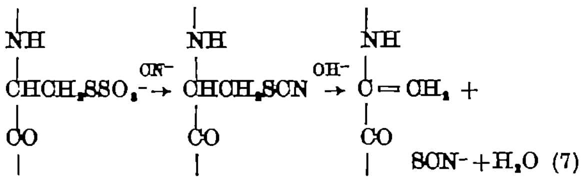
$$(HO_2C)(H_2N)CHCH_2SSCH_2CH_2SSCH_2CH(CO_2H)(NH_2)$$

(I)

Organic thiosulphates have been patented as agents for modifying reduced keratin[11]. Mixed disulphide formation occurs between the protein chains and the organic residue from the thiosulphate, while difunctional thiosulphates are thought to give cross-links between the chains of the kind shown in (I). Experiments of this kind have been carried out with soluble wool kerateine and various thiosulphates. It is of interest that the mixed disulphide of wool kerateine and cysteine is extremely labile in alkaline solution and becomes rearranged to cystine and the highly insoluble 'oxidized kerateine'. The same is also true of the kerateine–thioglycollic acid mixed disulphide.

The mixed disulphide of cysteine and benzyl mercaptan, which may be termed S-(benzylthio) cysteine, shows promise as an intermediate for the synthesis of cystine peptides. Analogously to S-(phenylthio) cysteine[12], it becomes rearranged to cystine and dibenzyl disulphide on refluxing in 6 N hydrochloric acid, or on gentle warming in a solution of anhydrous hydrogen bromide in acetic acid. It may be recovered unchanged from a solution in 6 N ammonia, but the solution in N sodium hydroxide deposits dibenzyl disulphide quantitatively after about one minute. That this rearrangement is catalysed by traces of thiol formed by alkaline decomposition is shown by the fact that the appearance of dibenzyl disulphide is greatly retarded if a small amount of a chloromercuri compound be present initially.

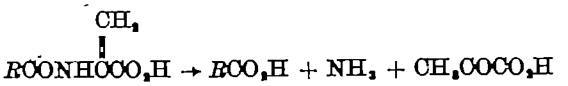
Specific fission of protein chains. The reaction of alkyl thiosulphates with cyanide to yield alkyl thiocyanates (reaction 4) has led to a potential method for the specific fission of peptide and protein chains at the cysteine or cystine residues. The method depends on the fact that the 'β-thiocyanoalanine' residues formed from *S*-sulphocysteine with cyanide are readily degraded to thiocyanic acid and 'dehydroalanine' (α-aminoacrylic) residues (reaction 7).



$$\mathrm{-NH-CH(CH_2SSO_3^-)-CO-} \xrightarrow{\mathrm{CN^-}} \mathrm{-NH-CH(CH_2SCN)-CO-} \xrightarrow{\mathrm{OH^-}} \mathrm{-NH-C(=CH_2)-CO-} + \mathrm{SCN^-} + \mathrm{H_2O} \quad (7)$$

β-Thiocyanoalanine residue   Dehydroalanine residue

It is well known that *N*-acyl dehydroamino-acids are readily split by dilute acid or alkali yielding the acyl compound, ammonia and a ketoacid[13]; for example:



$$R\mathrm{CONHC(=CH_2)CO_2H} \rightarrow R\mathrm{CO_2H} + \mathrm{NH_3} + \mathrm{CH_3COCO_2H}$$

In addition, much attention has been given to dehydropeptidases, which can bring about the same fission without causing hydrolysis of normal peptide bonds[14]. Promising results have already been obtained in applying this method to the *S*-sulpho derivatives obtained from various synthetic cystine derivatives, glutathione and insulin, and further work on these lines is in progress.

It is hoped to publish elsewhere a more complete account of these investigations.

ORIENTED TRANSFORMATIONS IN IRON OXIDES AND HYDROXIDES

By Prof. J. D. BERNAL, F.R.S., Dr. D. R. DASGUPTA and Dr. A. L. MACKAY

Birkbeck College Crystallographic Laboratory, 21 Torrington Square, London, W.C.1

It has been known for many years that, in the systems of hydroxides of some tervalent metals, notably iron and aluminium, there exist two series of crystalline structures, α and γ, the first of which on heating gives rise to hexagonal oxides (hæmatite, Fe_2O_3; corundum, Al_2O_3) and the second to cubic, spinel-like forms (maghæmite, or magnetic ferric oxide, and γ-alumina).

The nature of these transformations suggests that they take place, not by *de novo* recrystallization of the oxide, but rather by the shifting and re-stacking of structures already existing in the hydroxides. This mechanism has already been discussed by one of us for the case of the aluminium[1] and manganese[2] hydroxides. We have recently, in the course of a study of structures of magnetic minerals, been able to follow this transformation in some detail, as well as a further change from the γ-oxide form to the α-oxide, which also proceeds in an ordered way.

The starting material is the somewhat rare mineral lepidocrocite, γ-FeO(OH), specimens of which were provided by the British Museum (Natural History) and Oxford University Museum. Lepidocrocite was also prepared synthetically by various methods[3], of which the most successful was that of Welo and Baudisch[4], in which ferrous hydroxide was precipitated from ferrous chloride solution with pyridine and oxidized by passing a current of air through the solution. Rapid oxidation produces maghæmite at room temperature similar to that produced by electrolysis by Davey and Scott[5]. We have found it extremely difficult to prepare pure lepidocrocite. Most specimens are contaminated by maghæmite and gœthite, α-FeO(OH), and this may partly account for the instability of the precipitated hydroxide relative to the natural mineral.

Precipitated lepidocrocite began to lose water at 180° C. and was completely converted to maghæmite and some hæmatite at 200°, all maghæmite being converted to hæmatite below 250°. The natural crystals proved more stable. This corresponds to the observations of one of us[6] that the impure iron hydroxide limonite, which is mostly gœthite, loses water at 210° as against 250° for the pure mineral.

It was found that a single crystal of lepidocrocite could be heated in air to 235° without change, but that at 250° it became transformed to an oriented texture of a spinel phase and hæmatite. The former was very poorly crystallized, having a particle size, estimated from the line broadening, of 100 A.; its lattice dimension was $a = 8 \cdot 356 \pm 0 \cdot 003$ A, which is closer to that of maghæmite (8·350) than magnetite

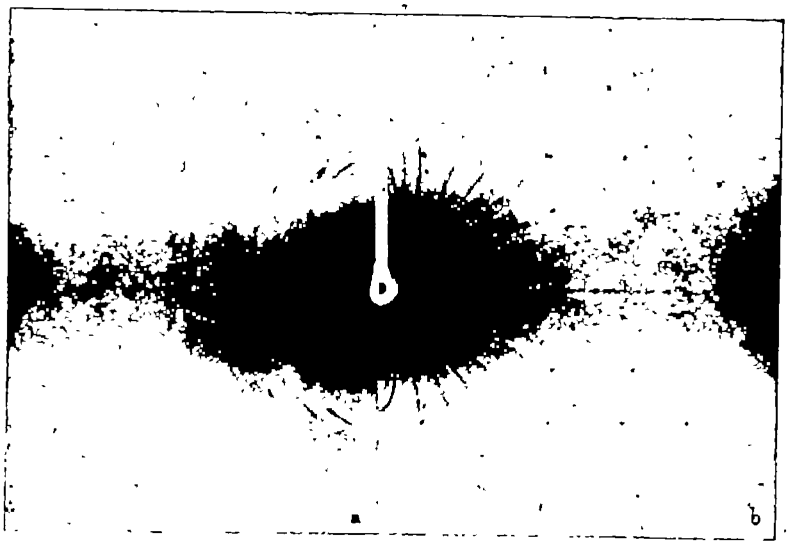

Fig. 1. (a) Natural lepidocrocite heated to 250°, and converted to maghæmite (diffuse spots) and hæmatite (sharp spots). Rotation photograph, cobalt radiation, 16 hr., about the [100] axis of original lepidocrocite. This axis has become a [100] axis of maghæmite and is approximately an $[04\bar{1}]$ axis of hæmatite
(b) Magnetite–ilmenite intergrowth unheated. Rotation photograph about a [100] axis of the magnetite. Copper $K\alpha$ radiation, 16 hr. exposure. Enlarged to correspond to left side of the figure

(8·396). However, the X-ray reflexions, such as (221) and (320), which distinguish maghæmite (space group $P2_13$ or $P4_332$) from magnetite (space group $Fd3m$), were not observed; but it seems more probable that the spinel phase should be disordered maghæmite than that it should be magnetite, Fe_3O_4, which would require the loss of 1/12 of a molecule of oxygen per FeO(OH) formula unit in the first stage of the transformation and a similar gain in the second stage. The nature of the mutual orientation is evident from the X-ray photograph (Fig. 1a) and is shown diagrammatically in Fig. 2. The maghæmite crystals form with their [001], [110] and $[\bar{1}10]$ axes parallel to the principal axes [100], [010] and [001], respectively, of the lepidocrocite crystal. The hæmatite crystals then grow with their [00·1] axes parallel to the [111] directions of the maghæmite and their $[1\bar{1}\cdot0]$ directions parallel to the $[1\bar{1}0]$ directions of the maghæmite. The sharpness of the X-ray diffraction spots from the hæmatite shows it to be much better crystallized than the maghæmite.

The dehydration of lepidocrocite on heating in air was followed on an electronically controlled thermo-balance (Northern Coke Research Laboratories, King's College, Newcastle upon Tyne) with simultaneous measurement of the magnetic susceptibility by the Curie–Chéneveau method. The rate of heating was 100° per hour. The half molecule of water began to come off at about 240° and the specimen weight became constant at about 300°. For synthetic lepidocrocite the corresponding temperatures were about 50° lower. The presence of a magnetic phase was detected immediately the loss of weight at 240° began. The apparent susceptibility increased rapidly to a maximum when the specimen was at about 290°, and then decreased steadily, becoming smaller than could be measured at 440°.

The mechanism of the transformation would appear to be as follows. Fig. 3 shows the similarity of the lepidocrocite structure to that of maghæmite (spinel type). The transition would require the removal of half the hydroxyl groups, together with the hydrogen atoms in the adjoining hydroxyl sheets, as water molecules, followed by a closing up of the (010) layers from 12·57 to 8·85 A., that is, by 30 per cent (1·86 A. per layer) in the [010] direction of the lepidocrocite, together with a shift of half an oxygen ion width (1·94 A.) in the [100] direction. The a- and c-dimensions of lepidocrocite differ by 0·30 and 0·11 A., respectively, from the corresponding periods of maghæmite, and the resulting strain may account for the smallness of the maghæmite crystals. Our observations establish that the formation of hæmatite is subsequent to that of maghæmite, for it is oriented in relation to the planes of the maghæmite and not of the original lepidocrocite. The second transformation does not involve any loss of material but only a re-stacking of the hexagonal close-packed oxygen atoms on the {111} faces of the maghæmite. In the process it is evident that some crystal growth occurs.

The orientation relation observed for the maghæmite–hæmatite transformation has also been verified by X-rays for the isomorphous magnetite (Fe_3O_4)–ilmenite ($FeTiO_3$) transformation, which occurs in natural titaniferous magnetite systems

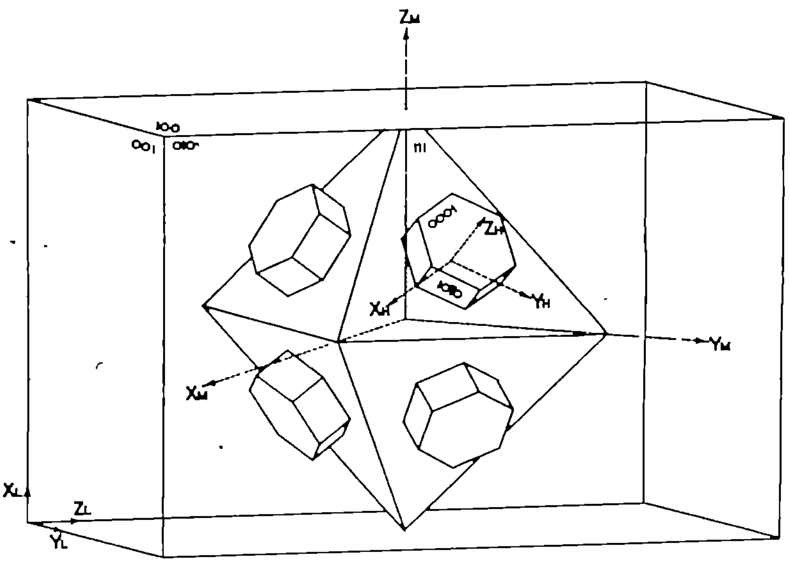

Fig. 2. Orientation relationships in the transformation lepidocrocite (L)—maghæmite (M)—hæmatite (H)

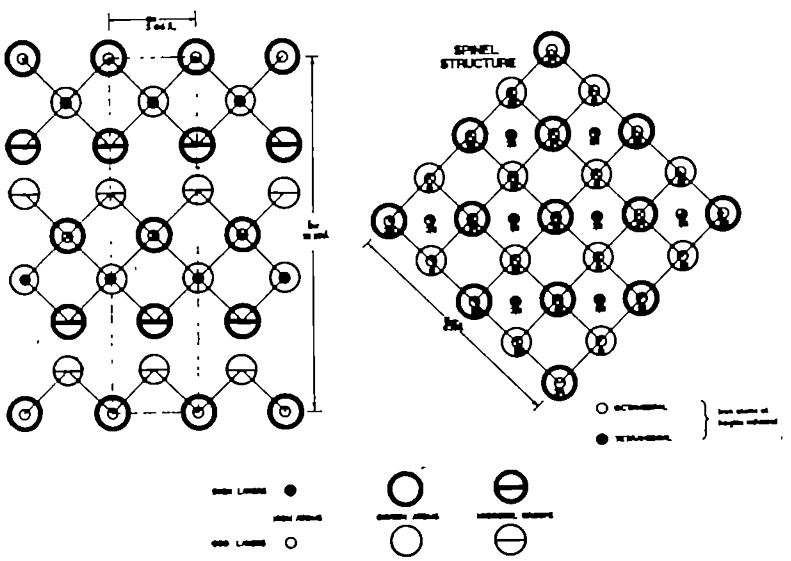

Fig. 3. Comparison of lepidocrocite and spinel structures. Unit cell outlined, a = 3·87 A

studied by Vincent[7]. We examined two types of single-crystal specimens derived from basic intrusions which were kindly supplied to us by Dr. E. A. Vincent. The first contained two spinel phases, magnetite and ulvo-spinel (Fe_2TiO_4) oriented very precisely parallel to each other. When heated to 500° the crystals partly homogenized to one spinel phase (with a = 8·446 A.). When heated to 950°, the homogenization appeared complete (with a = 8·432 A.).

The second specimen, which must have been derived by slow cooling from a single crystal, contained both magnetite and ilmenite phases. Here all the spots were perfectly sharp and the ilmenite crystals were oriented in relation to the magnetite. As the photograph (Fig. 1b) shows, this orientation is exactly as found in the maghæmite–hæmatite transformation (Fig. 1a) described above, with the [00·1] axes of the ilmenite (isomorphous with hæmatite) parallel to the [111] axes of the magnetite. Heating to 950° did not produce homogenization. One specimen was found with two parallel spinel phases oriented with respect to the ilmenite as just described.

These observations, taken together, go far to substantiate the idea that, whenever steric conditions permit, solid state transformations, even where material is lost to the system, proceed by a minimum rearrangement of the structures of single crystals, involving little more than the mechanisms of dislocation glides, such as produce stacking faults and twinning. This type of transformation is not limited to compounds of metals of fixed valency. Similar transformations occur[5] in the series $Mn(OH)_2$–$NnO(OH)$–MnO_2, while in the iron series it is highly probable that the original white precipitate of $Fe(OH)_2$ from ferrous solutions belongs to the γ-series, and the red precipitate of $Fe(OH)_3$ from ferric solutions to the α-series. It seems reasonable to infer, wherever powder photography indicates two series of transformations of the same chemical compound leading to different end-products, that oriented or epitaxial types of transformations are involved.

The work described forms part of a research programme on magnetic ores sponsored by the Department of Scientific and Industrial Research, to which we are grateful for financial support.

EXPERIMENTAL INDUCTION OF THE BREEDING SEASON IN A XEROPHILOUS BIRD

By Dr. A. J. MARSHALL

Department of Zoology and Comparative Anatomy, St. Bartholomew's Medical College, University of London

AND

H. J. de S. DISNEY

Department of Agriculture, Dodoma, Tanganyika Territory

ALTHOUGH there have been suggestions to the contrary, it is unlikely that the breeding seasons of truly equatorial vertebrates are controlled by photoperiodicity, although at 16° N. (Senegal)[1], and even at 3·22° S. (Tanganyika)[2], the sexual cycle of *Quelea quelea* (the red-billed weaver finch) has been advanced by artificial illumination. Rather, many equatorial and other species have evolved a reproductive response to rainfall, or its effects. There has been adduced, however, little evidence concerning the role of rainfall *per se*, as distinct from the various environmental effects (for example, the sudden appearance of green grass, green seeds, animal food) of which it is an essential cause[3].

Q. quelea is a sexually dimorphic, highly nomadic weaver-finch that occurs in flocks of up to one million strong over great areas of Africa below the 30-in. isohyet[4,5]. Such flocks cross the equator and may breed on either side of it irrespective of minor photofluctuations. Between March and June, 1956, five hundred young *Quelea* were trapped soon after leaving the nest in the Dodoma area (lat. 6° 11′), Tanganyika. The juvenile age-groups were distinguished by ringing, and one hundred birds were placed in each of four cages measuring 18 ft. × 6 ft. × 6 ft. These were furnished as follows:

Cage I: Nesting bush (*Acacia mellifera*) of traditional kind, *dry* seeds of white millet (*Panicum miliaceum*) and bulrush millet (*Pennisetum typhoideum*), trough-water, and long *dry* grass of the genus (*Cynodon*) the bird uses for building material.

Cage II: As Cage I, but equipped also with a sprinkler simulating natural rainfall for two hours a day (= approx. 0·5 in.).

Cage III: As Cage I, but additionally with fresh *green* grass-seeds, long *green* nesting grass and trays of just-germinated green millet.

Cage IV: As Cage III, but additionally with a sprinkler for two hours per day (0·5 in. of 'rain') and quantities of harvester termites (*Hodotermes mossambicus*), grasshoppers, and dipterous larvae.

The difficulty of maintaining supplies of green grass, green grass-seeds and live larvæ during the dry season was overcome by growing appropriate grasses under irrigation and establishing an insect hatchery. This plantation grass was augmented by fresh grass (*Echinochloa stagnina*) collected by Africans from a distant swamp and dispatched by goods train three times a week. Grasshoppers and termites were collected daily. The cages were 10–30 yards apart, and optically isolated by hessian screens and sorghum stalks. Food, grass and water were replenished twice a day.

The experiment was begun on June 30. In all groups the birds almost immediately tried to weave nests. Building was done only by the males, and in synchronized surges within groups. Frequently, too, there were synchronized demolitions followed again by concerted building. Weekly counts were made and after two months current nesting attempts were recorded as follows:

Date	Cage I	Cage II	Cage III	Cage IV
September 1	1	3	21	13

Thus, indications were obtained that for these birds (which were still physiologically incapable of reproduction) green grass is an important factor in nest building. It appeared to be physically impossible for long, brittle, dry grass to be used, and wild populations never attempt to do so.

The experimental procedure was now varied as follows: On September 10 all nests were demolished in Cages I and III. To Cage I, where building under dry conditions had been negligible, green nesting grass was added. From Cage III green seed and trays of germinated millet were eliminated so that both these cages now had dry food and green nesting grass. The following results were obtained:

Date	Cage I	Cage III
September 9	1	22
,, 10	—	—
,, 11	9	7
October 1	17	20

There is, then, good evidence of the importance of long green grass as a nesting stimulus. However, the above figures refer to nesting *attempts* in which imperfect structures were built. It was found that complete nests were made only when the grass had produced long stems (for the frame of the nest), long blades (for tying the frame together), and seed-heads.

Although rain did not raise the number of building attempts it did appear slightly to accelerate the assumption of breeding coloration in the female. In Cages II and IV the females began to change colour before the others, but in all cages the visible changes took three weeks. (It was considered inexpedient to handle the birds so it is possible that initial moult stages may have been unobserved.) In all experimental cages the females changed colour before the wild population. In a reserve cage provided with dry millet, resting bush, trough-water and no building material whatever, the colour changes were delayed and remained approximately in phase with those of the wild population. Therefore, it seems possible that close association with males engaged in the manipulation of nesting material may have exerted a stimulus that operated neurohumorally and accelerated colour change. In the experimental cages full nuptial colour was complete in both sexes before November 20 so that, even without rainfall, green grass or animal food, the birds were physically prepared for reproduction before the 'rainy season' expected in December or January.

The first eggs were laid (in Cage III) on December 24. One egg was found on the ground. The other was laid in a nest: it was incubated, developed an embryo, but was destroyed by intruder birds just before hatching. Before the initial ovulation only 4·01 in. of natural rain fell and for more than a month (Nov. 28–Dec. 31) there fell only 5·09 in.

This natural precipitation was negligible in quantity compared with the artificial rain provided in Cages II and IV and did not lead to reproduction in Cages I, II or IV. The manufacture of complete nests was slightly retarded in early January when our plantation grass failed to produce seeding heads. By January 28, however, stems bearing seeds were again available, and many nests were completed. More young appeared in Cage III on March 1 and 5, and on the latter date the first eggs hatched in Cage IV. The incubation period is twelve days and there had been no natural rain between Feb. 12 and March 1.

In Cage II (for months supplied with a daily 0·5-in. of artificial rain, dry food and dry nesting grass), a few birds at length managed to weave sodden dry grass into nests. One egg was found on the ground on April 12 and an egg was laid in a nest on May 14. This disappeared the next day, probably destroyed by intruders.

Altogether, thirty young were hatched in Cage III. As successive groups of young appeared, a temporary supply of insect food was provided but only five chicks were successfully reared. In Cage IV five young were hatched, of which none survived. Deaths were generally caused by the attacks of adults. The begging posture of the chicks somewhat resembles that adopted by soliciting females and this was often responsible for severe injury by neighbouring males. The 1956–57 rainfall was very unevenly distributed, with periods of no effective precipitation for as long as six weeks. The only reproduction that occurred in *Q. quelea* over an area of many hundred square miles was in our Cages III and IV.

The present initial experiment was hampered by the periodic failure of our plantation grass to mature sufficiently, by the collapse of the nesting bushes due to the ravages of weevils and, perhaps, by the presence in the cages of too many birds. However, from the above results it appears that:

1. There exists in *Q. quelea* an innate urge to build nests which, in the confines of a cage well supplied with food, will find expression within about three months of leaving the nest, and before individuals have assumed nuptial plumage.

2. Successful nest-building cannot take place until the environment provides green grass with stems and blades sufficiently long to be used by the males for weaving. By this time (and when the females will accept the nests) the green grass is seeding. It is not yet known whether the seed-heads exert a stimulus on the females. It has been previously shown[4] that the young are fed principally on green seeds from the age of five days, but that during the first five days of life the parents bring them insects (providing essential amino-acids). Yet this kind of protein food does not appear to constitute a stimulus to reproduction. Inevitably, of course, animal food becomes available at the same period as the seed-heads. Thus, if the nomadic flocks of *Quelea* find enough suitable green nesting grass, the amino-acids essential to the early development of the young will be there as well.

3. Experimentally, rainfall in itself lowers, rather than increases, the number of ovulations (but not the number of *complete* nests).

4. An internal rhythm of reproduction exists, and this controls in both sexes the assumption of sexual coloration of beak, soft parts, plumage and, in the male, the onset of sexual display, performed on or near the incomplete nest, that leads to copulation. This rhythm is modifiable by external conditions, including possibly rainfall and other external effects (for example, social stimulation). Many birds of both sexes came into breeding dress when only 5½ months old, and reproduction was shown to be possible at the age of nine months. Thus the breeding which occurs in this highly nomadic pest in southern Kenya in December and January could be by birds themselves hatched as recently as the previous March or April in Tanganyika.

Fuller observations, including particularly those concerning comparative gonad development in relation to external conditions and display in caged and wild populations, will be published elsewhere.

We are indebted to the director (Mr. J. R. Soper) and the assistant director (Mr. N. R. Fuggles-Couchman) of the Department of Agriculture, Tanganyika Territory, whose kind co-operation made our work possible. One of us (A. J. M.) was enabled to work in East Africa through the courtesy of the East African Fisheries Research Organization and its director (Mr. R. S. A. Beauchamp).

GENETICALLY-CONTROLLED DIFFERENCES IN CATALASE ACTIVITY OF DOG ERYTHROCYTES

By DR. A. C. ALLISON and W. ap REES

Medical Research Council Unit for Research in Cell Metabolism, Department of Biochemistry, University of Oxford

AND

G. P. BURN

Department of Biochemistry, Radcliffe Infirmary, Oxford

DURING the course of experiments on vitamin E deficiency[1], Drs. T. Moore and I. M. Sharman noticed that in the presence of dialuric acid the erythrocytes of some dogs became brown in the course of a few minutes while the erythrocytes of other dogs maintained their normal red colour for ½ hr. or longer. It occurred to us that this observation might be due to differences in the activity of the enzyme catalase in the erythrocytes; such differences had already been shown to exist[2]. It was supposed that, in the absence of sufficient catalase, hydrogen peroxide, produced by autoxidation of dialuric acid, might accumulate and oxidize the hæmoglobin in the erythrocytes to methæmoglobin, which is brown. On the other hand, if there were sufficient catalase in the erythrocytes, they would retain the red colour of oxyhæmoglobin.

Tests with dialuric acid were carried out using an adaptation of Gyorgy's technique for detecting hæmolysis in vitamin E-deficient animals[3]. Blood was collected in 0·2 *M* sodium citrate buffer, *p*H 7·4. The erythrocytes were washed twice in 0·9 per cent sodium chloride and the packed cells resuspended in 20 vol. of 0·9 per cent sodium chloride. The dialuric acid solution contained 1 mgm. per ml. in 0·2 *M* phosphate buffer, *p*H 7·4, with sodium as the only cation. Small test-tubes were set up containing 0·1 ml. dialuric acid solution, 0·15 ml. buffer and 0·25 ml. cell suspension. Each blood sample was tested in duplicate and with a control tube containing buffer only. The tubes were placed in a water-bath at 37° C. for 15 min. By this time the great majority of cell suspensions were either bright red or dark brown: tests on individual dogs always gave the same result. In an unselected sample of seventy-two dogs, twenty-six were found to have brown cells. The dogs tested included various breeds (Irish setters, spaniels, greyhounds and terriers) as well as mongrels, all of which were divided for the character. The results are insufficient to decide whether the frequency of brown erythrocytes varies from breed to breed.

The activity of the enzyme catalase in the erythrocytes was measured with hydrogen peroxide as substrate, using the technique described by Allison and Burn[4]. The results are expressed as the initial reaction velocity in m.mol. of oxygen liberated per ml. packed cells per min. The observed activities in

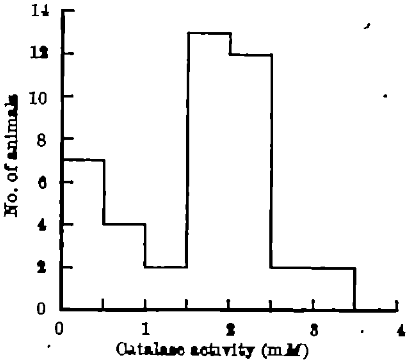

Fig. 1. Histogram showing the distribution of erythrocyte catalase activities in forty-eight dogs. Abscissa: catalase activity expressed as the initial reaction velocity in m.mol. oxygen liberated/ml. packed cells/min.

forty-two dogs are shown in Fig. 1. The results are in agreement with the report of Richardson *et al.*[2] on a small number of dog erythrocytes that "although the average value was low when compared with that of other species of animals, the relatively great differences in indices of bloods from individual animals are notable". Our results also confirm their conclusion that the mean erythrocyte catalase-level in dogs is about one-thirtieth of that in human erythrocytes. In the relatively wide range of activities encountered, there was evidence of a bimodal distribution; the level in any one animal tested at different times was remarkably constant. All the dogs the erythrocytes of which had become brown in the presence of dialuric acid had catalase-levels less than 1·5 m.mol./ml. cells/min.

Further experiments were undertaken to ascertain whether this difference is inherited. Through the kind co-operation of Mr. W. B. Singleton of the Canine Research Station, Kennet, Nr. Newmarket, Suffolk, and Mr. J. Scarnell, Wellcome Veterinary Research Station, Frant, Tunbridge Wells, Kent, blood specimens were obtained from seventy offspring of nineteen matings. In Table 1 the results of tests are classified according to whether catalase-levels fall into the high or low group (above or below 1·5 m.mol./ml. cells/min.).

Three main points emerge from Table 1. In the first place, most of the offspring of high × high matings fall into the high group, but four do not; all these had very low catalase activities. Second, there is a preponderance of high offspring among the high × low matings, which suggests that the high group of parents may have included some homozygotes as well as heterozygotes. Third, all but one of the offspring of low × low matings fall into the low category. The single exception had a catalase activity of 1·6 m.mol./ml. cells/min., which is narrowly within the high group.

Apart from the last finding (which could be due to a slight overlap between the range of distributions of high and low activities) the results are consistent with a simple mode of inheritance. We have supposed that there is a single pair of alleles *C*,*c* and that in the presence of *C* more catalase is produced than in the presence of *c*. On this hypothesis three genotypes would be expected, *cc*, *Cc*, *CC*, of which *cc* would show very little catalase activity while *Cc* and *CC* would show higher activities. If *C* were completely dominant to *c*, the activities of *CC* and *Cc* would be the same; otherwise the activities shown by the heterozygotes would be intermediate between those shown by the two homozygotes. In fact, three animals which might have been homozygous *CC* (because when mated with *cc* they had five or more offspring all of which fell into the high activity group) showed catalase-levels above 2·5 m.mol./m./min. All the parents in the high group who had offspring in the low group (that is, must have been heterozygous) had activities below 2·5 m.mol/ml./min. These findings suggest that the heterozygotes have enzyme activities intermediate between those of the two homozygotes. After the completion of this investigation, it was found that Putilin[5] had reported that high and low erythrocyte catalase-levels in cattle are controlled by a single pair of genes. Again, the activity of the heterozygotes is intermediate between those of the two homozygotes.

Table 1. Catalase-levels in Offspring of Various Matings

Mating type	No. of matings	Offspring	
		High	Low
High × high	7	21	4
High × low	10	23	16
Low × low	2	1	5

The catalase deficiency observed in some dogs may be confined to the erythrocytes: tests on a liver homogenate from one animal with a low erythrocyte catalase-level showed a slightly higher activity than tests on liver homogenates of two animals with high erythrocyte catalase-levels. It is noteworthy that the dogs with low erythrocyte catalase-levels showed no signs of hæmolysis, liability to infection or other disability. This is in contrast to the report of Takahara[6] that human subjects lacking catalase in their erythrocytes are subject to progressive oral gangrene.

Besides illustrating the quantitative effects on enzyme activity of the genes concerned, this situation is interesting from the point of view of population genetics. In the presence of the *c* gene relatively little catalase is produced, yet several breeds of dogs are polymorphic for the gene. Usually such genes are disadvantageous and remain at a low frequency in populations, but a few instances where they have become common are on record. Thus, about 15 per cent of rabbits lack the enzyme atropine esterase in their plasma and liver. According to Sawin and Glick[7] the capacity to split atropine is inherited in the form of a gene (*As*) located on the same chromosome as the gene (*E*) for the diffusion of black pigment in the fur. The character is incompletely dominant, since homozygotes (*As*/*As*) produce more enzyme than heterozygotes, while no activity at all can be detected in the other homozygotes (*as*/*as*).

The polymorphism of the *As* gene in rabbits and of the *C* gene in dogs and cattle could be explained if it were advantageous to have an enzyme activity intermediate between the two extremes, since the heterozygotes would then be favoured. Alternatively, pleiotropic effects of the genes concerned may have selective effects which have brought about the fixation of both pairs of alleles.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Effect of Exposure to Gamma-Rays on the Hygroscopicity of Sitka Spruce Wood

THE possibility of controlling insect attack in wood by exposure to gamma-radiation has recently been discussed by Bletchly and Fisher[1]. Although the practical applications of this method have still to be worked out and evaluated, any *in situ* treatment will inevitably expose the wood to the effect of the radiation, and with the development in Britain of the atomic energy programme, the exposure of wood to ionizing radiations is likely to become more common.

It is therefore of interest to see whether these radiations influence the properties of the wood itself, and as a first step towards this end the effect of exposure to gamma-radiation on the hygroscopicity of sitka spruce wood has been determined. Since nearly all physical properties of wood are affected by moisture content, it is probable that the changes in hygroscopicity may give some indication of the changes to be expected in other physical properties.

With the co-operation of the Technological Irradiation Group of the Isotope Division, Harwell, disks of sitka spruce approximately 19 mm. in diameter and 1 mm. in thickness along the grain were irradiated with cobalt-60 gamma-rays (energy 1·17 and 1·33 MeV.) to dosage-levels of 10^6, 10^7 and 10^8 rad. The temperature of the source was 35–40° C. and the time of exposure 200 hr. for the 10^8 rad dose (and *pro rata* for lower doses). The exposures were continuous, and since there was only limited ventilation the samples were in an atmosphere containing appreciable though unknown amounts of ozone. There was no change in the appearance of the samples after irradiation, but at the highest dose, the wood seemed to have become slightly brittle.

The equilibrium moisture content/relative humidity curves were determined on control and irradiated samples by a technique involving the use of McBain quartz spring balances. The adsorption curves for zero and 10^8-rad exposure are shown in Fig. 1, and it is apparent that there is a small reduction in equilibrium moisture content at all relative humidities with the 10^8-rad dose. The curves for 10^6 and 10^7-rad exposure are not shown, but there is some evidence of a slight though scarcely significant reduction at 10^7 rad; the curves for the control and 10^6-rad specimens are indistinguishable. Desorption curves were also determined and showed similar effects.

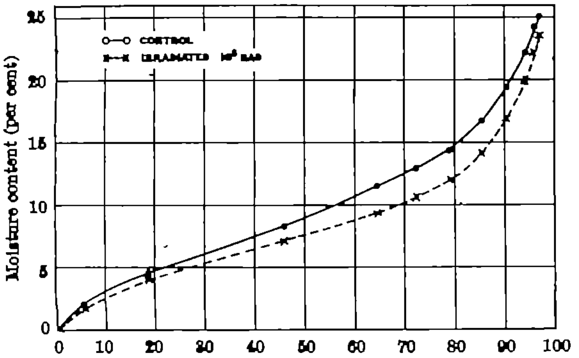

Fig. 1. Equilibrium moisture content/relative humidity curves in adsorption cycle for control and irradiated sitka spruce

It thus appears that the hygroscopicity (and possibly other physical properties) of wood are only affected by very heavy doses of radiation, and that at less than about 10^7 rad, the effect is negligible. This conclusion is in general agreement with the results of Lawton *et al.*[2], who studied the chemical changes in basswood on exposure to high-velocity electrons. They found that comparable exposures, approaching 10^7 r., were required before any chemical change became appreciable.

The doses of gamma-radiation mentioned by Bletchly and Fisher did not exceed about 60,000 rad and were often considerably less, whereas the present experiments involved doses greater by a factor of several hundreds. Thus any doses used for controlling wood-boring insects in practice are unlikely to have any significant physical effect on the wood itself.

The above work forms part of the programme of the Forest Products Research Board and is published by permission of the Department of Scientific and Industrial Research. We are grateful to Mr. T. Horne, of the Technological Irradiation Group of the Isotope Division, Harwell, for his co-operation in irradiating the samples and for comments and suggestions.

Absence of Lethal Radiation Effects following Massive Oral Administration of Plutonium

THE International Commission on Radiological Protection in its recommendations[1] assumed that radiation damage to the gastrointestinal tract from unabsorbed radioisotopes will be the critical factor in determining the maximum permissible concentration for many of these isotopes. Among the isotopes for which the gastrointestinal tract is considered the critical organ are a number of alpha-emitters. Since it seemed quite conceivable that the radiosensitive cells of the gastrointestinal tract might lie beyond the range of alpha-particles originating within the contents of the tract, experiments were initiated to determine the effect on the tract of an orally administered alpha-emitter.

For these studies plutonium-239 was administered to seventy-five rats, by stomach tube, as a hydrated polymer suspended in a nitrate solution at *p*H 2. Results obtained from preliminary acute toxicity studies within the lethal range are shown in Table 1. From these results it can be seen that death did not

Table 1. ACUTE TOXICITY TO RATS OF PLUTONIUM-239 ADMINISTERED INTRAGASTRICALLY

Dose (mc./kgm.)	Mortality (deaths/No. injected)	Time of death (days post-administration)
56	0/6	(none after six months)
88	1/4	1
93	2/4	1
100	2/2	1

occur from a dose less than 88 mc./kgm., and that all mortalities resulting from plutonium ingestion occurred within 24 hr. The time of death has been generally accepted as a criterion of the intestinal radiation syndrome[2], and in the case of rats, such deaths occur from four to seven days after irradiation with X-rays. Rats surviving the plutonium feedings have been observed for at least six months. Blood counts and body-weight changes have not varied significantly from those of control animals.

The oral plutonium dose of 88 mc./kgm. which resulted in only 25 per cent mortality can be calculated to have delivered at the surface of the contents of the small intestine a radiation dose of approximately 650,000 rem. This calculation is based on the same dosimetry assumptions made by the International Commission on Radiological Protection in establishing maximum permissible concentrations for poorly absorbed alpha-emitters, except that the constants used for describing the time of passage of the radioisotope through the gastrointestinal tract are those applicable to the rat[3] rather than those applicable to humans. Since this very large dose resulted in none of the symptoms characteristic of the intestinal radiation syndrome, it may be concluded that alpha-radiation originating within the contents of the intestine is largely ineffective in causing acute damage to the intestinal wall. At least to a qualitative degree, this conclusion should also be applicable to the situation of chronic exposure. It would therefore appear that for all practical purposes of hazard evaluation, alpha-emitting radioisotopes contained within the gastrointestinal tract may be ignored in calculating maximum permissible concentrations.

In contrast to these results with plutonium-239, similar studies involving the oral administration of yttrium-91 indicate that beta-particles originating within the contents of the gastrointestinal tract are approximately as effective as external X-irradiation in eliciting all of the symptoms of the intestinal radiation syndrome.

A more detailed account of these experiments will be published elsewhere. This work was performed under Contract No. *W*-31-109-*Eng*-52 for the Atomic Energy Commission. We acknowledge the technical assistance of Mrs. Alma L. Crosby.

Uptake of Benzpyrene by a Chromosomal Phospholipid

The uptake of 3,4-benzpyrene by cells has been of interest to many workers, particularly in view of the carcinogenic properties of this substance. Moreover, it is a fluorescent compound and has been used as a fluorochrome for lipids into which it will dissolve from a hydrotropic solution; caffeine is usually used for dispersing it finely in water, since alone benzpyrene appears to be almost completely hydrophobic. Berg[1] has used this method in a detailed and extensive study of the distribution of lipids in a wide range of normal and cancerous animal cells and in the root tips of *Allium cepa*. In order that the lipids should not be affected by his preparatory procedures, he fixed the tissues in formalin which had been stored over powdered chalk; chalk seems to have the same effect as calcium chloride, which is frequently added with the intention of maintaining a high concentration of calcium ions to immobilize lipids[2]. This method of fixation seems to be much favoured by histologists. The tissue was sectioned with a freezing microtome, and the sections were then stained with benzpyrene. After a very careful investigation, Berg was forced to conclude that in animal and plant nuclei lipids are not present except in the nuclear membrane, and that biochemical demonstrations of these compounds in extracted nuclei were due to contamination by the cytoplasm. Indeed, he found that the nucleus was the one region in cells that never showed uptake of benzpyrene.

While studying the histochemistry of lipids in meristematic plant cells, we have found that formalin, with or without the addition of calcium chloride, removes a lipid-protein complex from the roots and that afterwards the interphase and mitotic chromosomes contain no apparent lipid. The extracted lipid has been precipitated out of the used fixative, hydrolysed in alcoholic potassium hydroxide, and glycerophosphate has been identified by partition chromatography in the hydrolysate. A similar lipid has been obtained from calf thymus fixed in the same manner. When the tissues are fixed in Lewitsky's fluid (equal volumes of 10 per cent formalin and 1 per cent chromic acid) or in formalin containing ammonium reineckate, no lipid material is demonstrable in the fixative and the chromosomes react positively with lipid stains. These results have been obtained with the roots of *Vicia faba*, *Trillium grandiflorum* and *Scilla campanulata*[3].

Thus it seemed likely that in these plant species and in calf thymus there was a phospholipid, probably associated with the chromosomes[4], which was removed by fixing the tissues in formalin but was retained after fixation in Lewitsky's fluid. It was thought advisable to see if Berg's inability to find benzpyrene in nuclei could be due to the removal of this material by his fixative. Roots of *A. cepa* were chosen, since he had reported that the nuclei of these roots did not stain with benzpyrene; but those of *V. faba* and of *T. grandiflorum* were also studied because in these two species the phospholipid which can be extracted by formalin had been characterized. In all our experiments, the chromosomes in those roots which had been fixed in formalin took up little or no benzpyrene, depending on the duration of fixation (5 hr.–2 days), whereas those which had been treated with Lewitsky's fluid took it up strongly. Care was taken to ensure that the fluorescence observed was caused by the benzpyrene and not by the autofluorescence of the tissues, which varied with the species and with the fixation procedure.

To confirm that this phospholipid might be the cause of the discrepancy between Berg's results and ours, two tests were devised. In the first, pieces of calf thymus were immersed in an aqueous 'solution' of benzpyrene for three hours and were then rinsed thoroughly in water and fixed in formal-calcium. The precipitate which was obtained from this used fixative showed fluorescence due to benzpyrene. For the second test, pieces of calf thymus were fixed in formal-calcium, and the precipitate which was obtained by shaking the clarified fixative with chloroform was subjected to the Folch procedure[4], which was repeated to ensure complete removal of all matter which was soluble in water. The purified precipitate was dried on slides and treated with the benzpyrene 'solution' or with the caffeine solution alone; there was uptake of the benzpyrene by this material.

In preliminary studies on animal cells a similar situation to that in plant cells has been found, in that there is a distinct uptake of benzpyrene by the heterochromatic regions of nuclei in mouse liver fixed in Lewitsky's fluid but none in the same tissue fixed in formalin.

It seems likely, therefore, that in all those experiments in which tissues have been fixed in formalin and in some other fluids[3] there has been loss from them of a lipid component which appears to be present on the chromosomes and which is capable of concentrating benzpyrene from an aqueous 'solution'. It is probable that this is the reason why Berg[1] failed to find uptake of this carcinogen by nuclei. It should be pointed out, however, that although there is some evidence[2] that this lipid is indeed present in life in the heterochromatic regions of the interphase nuclei and on all parts of mitotic chromosomes, final proof is lacking as yet.

We wish to thank Prof. J. T. Randall for giving us the facilities for this work, and Dr. K. S. Dodds for his encouragement. We are grateful to Dr. H. B. Fell for her advice and interest during all stages of the work. We also thank Dr. P. E. Levers for a helpful discussion. A fuller communication on this subject will be presented later.

Intracellular Incorporation of Iron-59 into the Root Cells of *Pisum*

Kessler recently reported[1] that in the leaves of several fruit trees there is an intimate connexion between the level of soluble iron and that of deoxyribonucleic acid. During the past two years we have been assembling data which are of immediate relevance in this connexion.

We have shown[2] that when detached pea roots are cultured in an iron-deficient medium growth stops as a result of an arrest in cell division. The cessation of division occurs abruptly, and undoubtedly coincides with a state in which the free inorganic iron content of the tissue has been reduced to a level which will not support the further duplication of cells. When iron is restored to non-dividing deficient roots division is immediately reactivated. Moreover, at the time when division ceases, the only part of the root apparently affected by the deficiency is the extreme apical meristematic region. At the stage when growth ceases, the body of the deficient root is virtually indistinguishable metabolically from that of a normal root. We have assembled evidence which is compatible with the hypothesis that the failure in division is a consequence of a restriction in the synthesis in the meristem of a cytochrome oxidase system, although the evidence does not exclude the alternative interpretation that the restriction in synthesis is a result of the arrest in division.

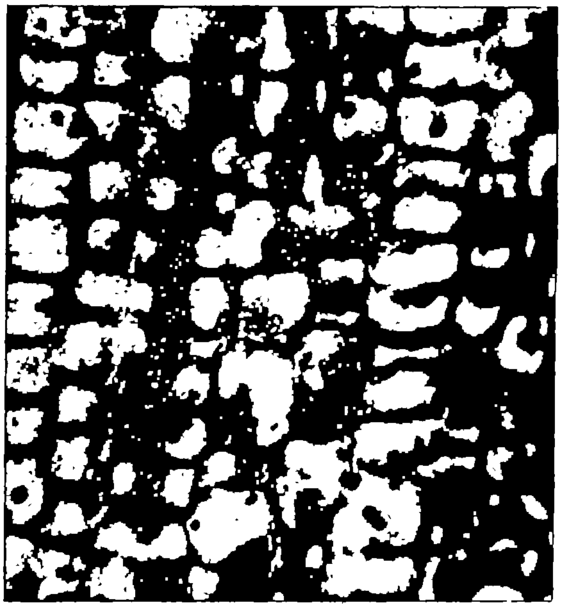

Fig. 1

Since iron affects division, the distribution of the metal in the cell becomes a matter of some importance, and this has been examined by autoradiography. In this series of observations iron-59 has been used. The roots of two-day old pea seedlings were immersed in a solution containing radioactive iron (0·1 and 1·0 µc./ml. of iron-59) and they were continuously aerated during an uptake period of 10–12 hr. at 25° C. After treatment the terminal centimetre was excised from each experimental root. The isolated tips were washed, treated with appropriate fixatives and sectioned after embedding in paraffin wax. After washing, following removal of the paraffin, the sections were covered with Kodak *A.R.*10 fine grain stripping film and autoradiographs prepared by the method of Doniach and Pelc[3]. After exposure for 10–30 days in a refrigerator the autoradiographs were developed and the sections stained with a Leishmann–Giemsa mixture.

Fig. 1 shows a photomicrograph of a longitudinal section of a pea root supplied with iron-59 at a concentration of 0·1 µc./ml. and treated with Zirkle's fixative[4]. It will be seen that the greatest aggregations of developed silver grains are over the nuclei, and it is clear that in the final preparation the relative concentration of iron in the nucleus is greater than it is in the cytoplasm. Similar results were obtained when absolute alcohol or a formalin calcium chloride mixture was used as the fixative but not when acetic-alcohol was used or when preparations made after neutral fixation were treated with 1·0 *N* hydrochloric acid. The possibility was explored that the accumulation of iron in the nucleus was a consequence of fixation. In one series of experiments the radioactive iron was supplied with the fixative, but this did not yield localization in the nucleus, and the possibility that the distribution shown in Fig. 1 is an artefact may, therefore, be disregarded.

Similar results to those described above have been reported by Poulson and Bowen[5], who found that iron-59 is preferentially incorporated into the nuclei of *Drosophila* and that it is not dislodged by neutral formalin alcohol mixtures or by fat solvents like dioxane. Kirby[6] also showed that the deoxyribonucleic acid isolated from rat liver nuclei carried a higher concentration of iron and manganese than did the whole liver.

It may be emphasized that the technique used here does not show the distribution of iron in the cells of intact tissues. In particular, the free soluble iron is undoubtedly dispersed by the preparative procedures. The results of this and other investigations, however, do show that iron is normally present in the nucleus in a form of combination which is not disrupted by neutral fixation. Thus, it is probable that certain nuclear components cannot be elaborated in the absence of iron, and this is at least consistent with the conclusion based on independent evidence that iron is essential for the progress of cell division. The results of Kessler[1] suggest that the promotion of division may be the effect of an influence of iron in the synthesis of deoxyribonucleic acid or in promoting the combination of this compound with other components of the nucleus. The second possibility is suggested by a conclusion reached by Kirby, who, in a preliminary note, states that heavy metals like iron, manganese and zinc may promote the linkage of deoxyribose nucleic acid with protein.

Secretion of Heparin by Mast Cells

THE granula of mast cells are known to contain mucopolysaccharide heparin[1]. It is active in the mechanism of the coagulation of blood and, moreover, according to more recent research, participates in the clearing of lipæmic serum as a component of the clearing factor[2]. The mechanism of liberation of heparin from the granula of mast cells was hitherto unknown. Degranulation of mast cells is not followed by disturbances in blood coagulation, even if it is extensive[3,4].

The liberation of heparin from the mast cells of rats was stimulated by intravenous injections of oil emulsion (Ol. olivae steril., 20·0 gm.; mucini e lini, 1·0 gm.; merthiolati, 0·01 gm.; aquæ redest. ad., 100·0 ml.) amounting to 2 ml./150 gm. weight. The control series of rats was treated in the same way with the exception of olive oil in the solution injected. To trace the level of all the serum lipids a modified thymol reaction at pH 4·2 was employed[5]. The results obtained by Moeller *et al.*[6] show that an oil emulsion administered in this way produces the clearing factor. Mast cells were examined in preparations of mesenteries which were carefully stretched on the slide, fixed with methanol and stained with an alcohol solution of toluidine blue[7].

An increase of the total lipids of the serum was observed within 4 hr. after the injection. 8 hr. later, the level was again normal. Characteristic were the changes in the mast cells of mesenteries in the lipæmic phase. The cytoplasm of the mast cells was condensed and the granula densely accumulated. Their stainability was equal. Some of the mast cells had pseudopodia-like protuberances with densely accumulated granula, gradually separating from the cytoplasm of the mast cell. Less frequent was the secretion of single granula. Free conglomerates of granula were afterwards phagocytosed by macrophages. The metachromatic substance, that is, heparin, was liberated from the mast cells and also from the macrophages by the lysis of granula. In the course of the lysis the granula of mast cells disappeared. The liberated metachromatic substance filled the cytoplasm of the mast cell or even the macrophage in the form of amorphous material, which again was diffusing through the cell membrane into the neighbouring regions. It seems that the observed lysis of granula is in fact a proteolysis. It produces a splitting of the protein component of granula, demonstrated *in vitro* by Zollinger[8], and thus also releases heparin in an amorphous form. In this connexion, we would refer to the experiments of Ungar and Damgaard[9] demonstrating the correlation between proteolysis and the liberation of heparin in anaphylactic and anaphylactoid reactions in tissue sections *in vitro*. Lysis was observed even in the mast cells of fat tissue. In this case there was an accumulation of metachromatic material between the

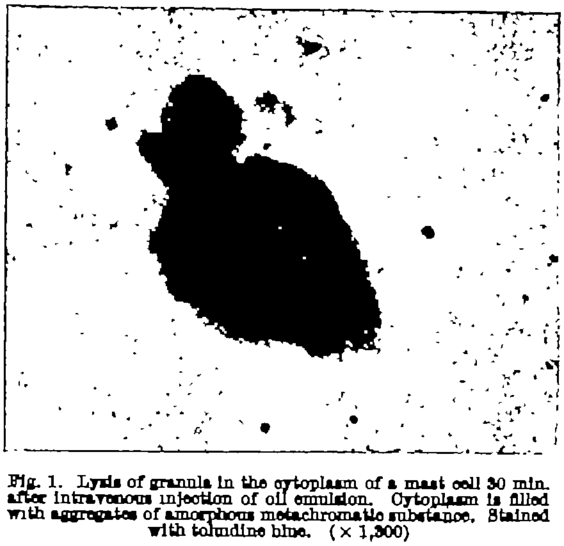

Fig. 1. Lysis of granula in the cytoplasm of a mast cell 30 min. after intravenous injection of oil emulsion. Cytoplasm is filled with aggregates of amorphous metachromatic substance. Stained with toluidine blue. (× 1,300)

membranes of the neighbouring adipose cells. After lysis in the mast cells and the elimination of their metachromatic material a new granulation was formed. The cytoplasm then contained tiny, thinly dispersed, nearly orthochromatically stained granula. After the lipæmic phase and similarly in the mesenteries of those rats to which the control solution was administered the results were negative.

From these observations we may conclude that experimental lipæmia resulted in the secretion of conglomerates of granula and in their subsequent phagocytosis, and further in a lysis of granula in mast cells and macrophages. The lysis caused the destruction of the protein component of the granula and the liberation of amorphous metachromatic material, that is, heparin, from the cell into its neighbourhood.

I have to thank Dr. L. Sobotka for preparing the emulsion and Dr. M. Pospíšil for determining the lipids in the serum.

Acriflavine as an Effective Agent for eliminating *F*-factor in *Escherichia coli K*-12

The artificial elimination of *F*-factor in *Escherichia coli K*-12 was obtained by treating *F*+ cells in a cobalt- or nickel-containing medium[1]. Of the two methods described in that communication, the direct method was difficult to apply to some strains derived from *K*-12, because the facility of conversion of *F*+ cells to *F*− cells varied with the strains used. On the other hand, the resistant-isolation method consistently gave *F*− cells, but was somewhat tedious, because the development of resistance to cobalt or nickel was very slow. Recently, however, it has been found that acriflavine is more effective for converting *F*+ cells into *F*− than cobalt or nickel and other metals (Ikoma, I., unpublished work).

An overnight culture of *F*+ cells is inoculated into a nutrient broth containing 'Kyokuto' broth 10 gm., 'Kyokuto' peptone 10 gm., sodium chloride 2 gm., and distilled water 1 litre or 'Difco' broth 10 gm., 'Difco' peptone 10 gm., and distilled water 1 litre, with a sublethal concentration of acriflavine (20 μgm./ml.) and incubated overnight at 37° C. The experimental culture contained about 1–3 × 10^7 cells/ml. and the control culture contained about 1 × 10^9 cells/ml. The cells were streaked on to the nutrient agar plate and well-isolated colonies grown on it were picked up one by one. Then, their compatibilities[2] were tested by crossing with *Y*-70*F*+ and *Y*-70*F*−, respectively. In this way, it was found that the majority of colonies exposed to acriflavine were fertile with *Y*-70*F*+, but infertile with *Y*-70*F*−, although untreated control cells were fertile with both strains (Table 1).

Table 1. Efficiency of Artificial Elimination with Acriflavine

Strains	Concentration of acriflavine (20 μgm./ml.)	None (control)
Y-40	40/40*	0/40
58–161	20/20	1/20
1023	6/10	0/10
AM	10/10	0/10
K-12†	10/10	0/10

* *F*− colonies found/total number of colonies tested.
† *K*-12 *F*− strains isolated by this method were infertile with *Y*-70*F*+ in *SRP* method (ref. 3). This was an unexpected result.

Table 1 shows that acriflavine is very effective as an *F*-eliminating agent. In fact, even the strains which were very stable to the metal treatment were found to be easily converted into *F*− cells by this method. The efficiency of conversion, however, was reduced when minimal medium (glucose–Simmon's medium) containing a sublethal concentration of acriflavine (5 μgm./ml.) was employed.

In the course of these experiments, some 'compatibility mutants' were obtained.

(1) *Intermediate strains*. Intermediate strains (*Fi*) were obtained in selecting resistant cells to cobalt, nickel and other metals[1], and by treating *F*+ cells with acriflavine for a short time (for example, *Y*-40*F*+ strain was treated in the broth containing 20 μgm./ml. acriflavine for 5–10 hr. at 37° C.). *Fi* was fertile with both *F*− and *F*+, but its fertility in the cross *F*− × *Fi* was lower than that in the cross *F*+ × *Fi*. Thus, *Fi* can be distinguished from both *F*+ and *F*− by its recombination behaviour. *Fi* strains were obtained from the various strains of *K*-12, such as *Y*-70*F*+, 58–161*F*+, *Y*-40*F*+ and *AMF*+. Table 2 shows an example.

Table 2. Fertilities of *Y*-40*F*+, *F*− and *Fi*

Parents	*Y*-40*F*+	*Y*-40*Fi*	*Y*-40*F*−
Y-70*F*+	+	++	++
Y-70*F*−	++	+	−

++, Very fertile; +, fertile; −, sterile

Fi was not the mixture of *F*+ and *F*− cells, since by the method of repeated isolations of a single colony, no evidence was found of a mixture of *F*+ and *F*− colonies, and each colony of these isolates showed the same behaviour as its parent *Fi*. However, a few isolates showed the fertility of *F*+, suggesting a spontaneous reversion of *Fi* to *F*+. The change from *F*+ to *F*− should involve a series of intermediate stages of *Fi*. Therefore, the *F* status of *Fi* shown in Table 2 is between *F*+ and *F*− as regards mating behaviour. The simplest explanation for the *Fi* state is that it may be due to a diminished number of *F* particles through the action of acriflavine, as in the case of yeast[4].

(2) *Hfr*− *strains*. *Hfr*− strains were obtained from *Hfr* (Hayes's strain) by three successive transfers in the nutrient broth containing 20 μgm./ml. of acriflavine or by the procedure of the resistant-isolation method[1] after forty transfers in the cobalt-containing medium. *Hfr*− resembles *F*− in its recombination behaviour in both fertility and compatibility; thus it is fertile with *F*+ (about 10^{-7}) and infertile with *F*−. Moreover, when isolating *Hfr*−, a special strain *Hfr-i* resembling *F*+ in both fertility and compatibility was obtained. The differences between *Hfr*− and *F*−, or *Hfr-i* and *F*+, are now under investigation.

One explanation for these phenomena is that *F* may be cytoplasmic particles or virus-like agents which are perhaps controlled by a gene or genes in the nucleus. *F* particles may play a part in chromosome transfer at a certain stage of its life-cycle, and, the more F particles are present in a cell, the more donor characteristics are shown in it, while the less F particles are present in a cell, the more recipient characteristics are expressed in it. It may be assumed that the relation between F particles and the mating behaviour of the host cell is analogous to that between kappa particles and the killer character in *Paramecium*[5]. Lederberg has also suggested in his recent review[6] that the production of $F-$ from $F+$ by the soft-agar passage is analogous to the loss of kappa from a rapidly grown clone of *Paramecium*.

We thank Prof. H. Kikkawa and Prof. S. Inoki for advice and criticism during the course of work.

Variation in the Time of Release of the Ovarian Development Hormone in *Aëdes aegypti*

EVIDENCE for the release of an ovarian development hormone during a critical period following a blood meal has been derived from ligation and decapitation experiments in both anopheline[1,2] and culicine[3] mosquitoes. In *Aëdes* (*Stegomyia*) *aegypti* (L.) development of the ovaries beyond the resting-stage (stage 2)[4] consists of a two-step process of initiation and promotion[3]. Development up to stage 3 is initiated in some way within minutes of taking a blood meal; but promotion of the oocytes from stage 3 to maturity (stage 5) must, apparently, await the release of a hormone, which at 28° C. occurs during a critical period 8–14 hr. later.

Little is known about the actual duration of the critical period in each mosquito. In the previous work[3] it usually occurred within these time limits, but varied from mosquito to mosquito; few of those decapitated at less than 8 hr. after a blood meal developed the oocytes to maturity, whereas most of those decapitated at 14 hr. or more did so. Between these extremes there was an increasing but variable number of mosquitoes which developed their oocytes to maturity.

In the work referred to above the mosquitoes were isolated in tubes as 'dry' pupae[5] and the emerging adults were maintained on moist raisins before being given their first blood meal. Work now in progress, however, indicates that previous fruit-feeding delays the onset of the critical period.

Daily lots of twenty-four 'dry' pupae of a strain of *A. aegypti* originating from Lagos, Nigeria, were isolated and divided into two groups, A and B. On emergence (day 0) raisins were given to the adults of group A for a period of 2 hr., but were withheld from those of group B. A trace of fruit juice was still visible in the ventral diverticulum[6,7] of the mosquitoes of group A on day 2, when both groups were given a blood meal and kept at 28° C. Four mosquitoes from each group were then decapitated every 20 min. up to 14 hr. after the blood meal. An extra number of group A mosquitoes were later added in order to allow the situation in this group to be followed up to 16 hr. As previous (unpublished) work on this species had shown that decapitated mosquitoes do not lay the eggs which they may have developed (even if previously mated), both groups were dissected on day 4 to see what proportion contained mature oocytes. Survival in the fruit-starved group was not so good as in the other, but mosquitoes of either group dying prematurely were excluded from consideration. The results, grouped on a 2-hr. basis, are shown in Table 1. None of the 173 negatives had developed their oocytes beyond stage 3.

These results, which were obtained from larger numbers than those in the previous experiments[3], indicate that the critical period in fruit-fed mosquitoes occurs mainly between 6 and 12 hr. after the blood meal. The critical period, however, in the fruit-starved mosquitoes, reared and blood-fed at the same time and at the same age as the fruit-fed mosquitoes, occurs mainly between 4 and 8 hr. after the blood meal. This delay and increased variation in the time of hormone release in the fruit-fed mosquitoes is the type of result which might follow if the filling of the diverticula with fruit juice by an uncontrolled and variable amount interferes with subsequent release of the ovarian development hormone.

It seems possible that the ovarian development hormone is normally released in response to stretching of the abdomen or the stomach with blood. Partial distension of the abdomen by filling of the diverticula with fruit juice may perhaps lead to premature release of the hormone and to its dissipation before the blood meal is taken; or distension of the ventral diverticulum may limit the amount of blood that can be taken into the stomach, and so affect a quantitative relation that may exist between the degree of stretching of the stomach and the time of hormone release. It is possible, however, that the presence of fruit

juice or its derivatives acts in a more indirect way; it may be mentioned that transmission of kala azar by the blood-sucking sand fly *Phlebotomus argentipes* Annandale and Brunetti is influenced by fruit feeding[8].

The implications of these findings are now being studied. In the meantime it is clear that much more consistent results are obtained when this uncontrolled variable is removed. Other work has failed to produce evidence for an ovarian development hormone in *A. aegypti*[5], but it is not known how far this failure may have been due to differences in technique.

Hæmagglutinins in *Calpurnia aurea*

AGGLUTININS acting strongly on suspensions of human group A and B erythrocytes in isotonic saline, and weakly or not at all on those of group O, are present in the seeds of *Sophora japonica*[1], *Coronilla varia*[1], *Crotalaria striata*[2], and in recently harvested samples of *Bandeiraea simplicifolia*[3]. The agglutinins of *Sophora japonica*, *Coronilla varia* and *Bandeiraea simplicifolia* act more powerfully, and to much higher titres, on B cells than on A cells; the reverse being true of those of *Crotalaria striata*.

During an investigation of agglutinins in plants available in Britain, another source of anti-(A+B) agglutinins was found in the seeds of *Calpurnia aurea* (butterfly bush or South African laburnum). The agglutination titres of crude isotonic saline extracts of these seeds (1 vol. seed material : 10 vol. saline) for saline suspensions of human erythrocytes are: A_1, 256; A_2, 32; B, 128; O, nil. Their general serological properties are similar to those of the agglutinins previously described. A single agglutinin is present, which can be absorbed by either A or B erythrocytes and eluted therefrom, the eluates having the same properties as the original extract. Treatment with A or B blood group specific substance, or with the simple sugars N-acetylgalactosamine and D-galactose, which are structurally related to the A and B substances respectively[4], inhibits activity with both A and B cells. L-fucose, N-acetylglucosamine and L-galactose do not inhibit when tested in similar concentrations. Unlike those previously described, the agglutinins are almost equally active with A_1 and B cells; O cells are not agglutinated when kept at 0° C. overnight or when suspended in albumin. Papainized O cells, however, are weakly agglutinated.

It appears that these agglutinins are better adapted to the chemical configuration common to the human blood group antigens A and B than any previously obtained from seeds; that is, they provide the hitherto closest approximation to the 'cross-reacting' or 'anti-C' agglutinins of certain human O sera[5].

Full serological details, and a discussion of the possible value of these agglutinins in routine blood grouping and blood group research, will be presented elsewhere.

An Investigation of an Action of Penicillin

PREVIOUS work[1] has suggested that amiphenazole (2 : 4-diamino-5-phenylthiazole hydrochloride, 'Daptazole', 'DHA 245') may enter, after a period of delay (1–3 weeks), into the thiamine metabolism of weanling rats maintained on a thiamine-free diet.

The expectation that penicillin, which is a 2 : 4 : 5 trisubstituted thiazolidine derivative, might likewise influence biological processes requiring thiamine, was assessed by its ability to support the growth, in the absence of thiamine or its thiazole moiety (4-methyl-5-hydroxyethyl-thiazole), of the mould *Phycomyces blakesleeanus*[2] and the weanling rat (40–50 gm.)[1,3].

Table 1 indicates that the presence of penicillin, thiamine or its thiazole moiety was essential for the growth of the mould during a 14-day period at 20° C. on an artificial medium[2] containing the pyrimidine moiety of thiamine (2-methyl-4-amino-5-ethoxymethyl pyrimidine).

Penicillin can therefore replace the thiazole moiety of thiamine as a growth factor for the mould.

Table 1. EFFECT OF PENICILLIN ON THE GROWTH OF *Phycomyces blakesleeanus*

Basal medium[2] plus	Degree of growth (20° C.) after 14 days
No added factor	—
Pyr (4×10^{-7} *M*)	—
Pyr (4×10^{-9} *M*) + Th (4×10^{-9} *M*)	++
Thiamine (4×10^{-9} *M*)	++
Pyr (4×10^{-7} *M*) + Pen (4×10^{-4} *M*)	++

— signifies no growth
++ signifies growth with aerial hyphæ
Pyr = 2-Methyl-4-amino-5-ethoxymethyl pyrimidine
Th = 4-Methyl-5-hydroxyethyl-thiazole
Pen = Crystalline sodium benzylpenicillin

The concentrations of penicillin and the thiazole moiety of thiamine or thiamine required to give a comparable weight of mycelium were in the ratio of 100,000 to 1.

Further, penicillin (4×10^{-4} *M*) supplemented a suboptimal concentration of the thiazole moiety of thiamine (4×10^{-9} *M*) to give an increased mycelial weight.

Table 2 illustrates the beneficial effect of intraperitoneal administration of penicillin, either alone or with the pyrimidine moiety of thiamine, on weanling rats maintained on a thiamine-free diet[4]. It both delayed the onset of thiamine deficiency and

Table 2. EFFECT OF PENICILLIN ON THE GROWTH OF THE THIAMINE-DEFICIENT RAT

All rats maintained on a thiamine-free diet. Twelve animals in each group. All drugs given intraperitoneally

Group	Drugs administered (mgm./kgm.) thrice daily Pen	Pyr	Onset of thiamine deficiency symptoms	Reversing drugs (mgm./kgm.) Thrice daily Pen	Pen	Pyr	Single dose thiamine (2 mgm.)
1	—	—	2–3 weeks	—	—	—	+
2	—	—	2–3 weeks	80	—	—	+
3	40	10	>9 weeks	—	40	10	+
4	20	5	>9 weeks	—	20	5	+
5	80	—	>7 weeks	—	—	—	+

Pyr = 2-Methyl-4-amino-5-ethoxymethyl pyrimidine
Pen = Crystalline sodium benzylpenicillin

reversed the symptoms of thiamine avitaminosis induced by withdrawal of treatment. Deficiency induced by withdrawal of penicillin treatment was reversed by a single dose of thiamine (2 mgm.).

Further, thrice-daily intraperitoneal administration of penicillin (80–240 mgm./kgm.) terminated pre-mortal convulsions of severe thiamine deficiency and effected recovery in several such animals.

The gain in weight over seven days of a group of thiamine-deficient rats (group 2) receiving penicillin (80 mgm./kgm. thrice daily), compared with that following the single dose of thiamine (2 mgm.), suggests a conversion of penicillin into thiamine or a beneficial thiamine analogue of the order of 1 per cent.

The possibility that the growth-promoting effect of penicillin may be due to its contamination with thiamine or its thiazole moiety was excluded by the results of photofluorometric, chromatographic and ultra-violet spectrophotometric analysis. The thiamine content of the penicillin used was less than 2 mμgm./gm., that is, less than 1/1,000 that required to produce the weight of mould and less than 1/50,000 that required to support the growth of rats[5] under the experimental conditions.

These results, and the fact that *Staphylococcus aureus*, like *Phycomyces blakesleeanus*, is dependent on thiamine or its thiazole and pyrimidine moieties[6] have suggested that penicillin resistance of *Staphylococcus aureus* may be associated with a change of the thiamine metabolic pattern of the organism to one more closely resembling that of *Phycomyces blakesleeanus*. This hypothesis is at present under investigation.

We thank the staff of the Antibiotics Section of the Commonwealth Serum Laboratories (Melbourne) for the chromatographic and ultra-violet spectrophotometric analyses.

Identification and Distribution of 5-Hydroxytryptamine in a Sea Anemone

5-HYDROXYTRYPTAMINE is widely distributed in Nature and has been found in members of different groups, including vertebrates, molluscs and tunicates[1]. It has also been detected in the venoms of Arthropoda, for example, wasps[2] and scorpions[3]. In plants, it has so far been identified in the dicotyledons cowhage[4] and nettle[5]. In the present experiments we have identified 5-hydroxytryptamine in the tentacles, column (body wall), and in the structures of the coelenteron (comprising mesenteries, gastric filaments, gonads, acontia, etc.) of the sea anemone *Calliactis parasitica*. The coelenteric structures contained by far the highest concentration and the tentacles the least. In experiments on two different batches of *Calliactis parasitica*, the 5-hydroxytryptamine content of the coelenteric tissues was 500 and 600 μgm./gm. freeze-dried tissue, whereas the tentacles of the same animals contained 7 and 6 μgm./gm. respectively (Table 1).

Table 1. AMOUNTS OF 5-HYDROXYTRYPTAMINE IN SEA ANEMONE *Calliactis parasitica*

Preparation	No. of animals	Test	5-Hydroxytryptamine (μgm./gm. freeze-dried tissue) Tentacle	Column (body wall)	Coelenteric tissues
I	5	Rat uterus	10	—	—
II	9	Rat uterus	12	30	—
II	9	Guinea pig ileum	8	25	—
III	7	Rat uterus	6	36	600
IV	4	Rat uterus	7	15	500

The identity of 5-hydroxytryptamine in the tissue extracts of *Calliactis parasitica* was established pharmacologically by their actions on the isolated rat uterus and guinea pig ileum. The effects on the rat uterus were completely antagonized by lysergic acid diethylamide. The active material was chemically indistinguishable from 5-hydroxytryptamine by its R_F values on paper chromatograms developed in butanol/acetic acid[7] or in *iso*propanol/hydrochloric acid[8] solvents. It was identical in its ultra-violet absorption, in its colour reactions with ninhydrin, Ehrlich's reagent, Pauly's reagent, and in the green fluorescence reaction described by Jepson and Stevens[9]. Also, its ultra-violet absorption spectra at various pH values agreed closely with those reported by Rapport[10] for 5-hydroxytryptamine.

In a recent study of coelenterate toxins, Welsh[6] stated that the tentacles of the sea anemone, *Metridium senile*, contained a substance resembling 5-hydroxytryptamine in its pharmacological properties, and that extracts of the body-wall contained much less of this activity. We have studied *Metridium senile*, and also *Anemonia sulcata*, but found that 5-hydroxytryptamine was either completely absent from their tissues or present in amounts too small to permit a definite identification. Heated, acidified extracts of *Anemonia* and *Metridium* did contain a smooth-muscle stimulant, the action of which on the rat uterus, however, was not antagonized by lysergic acid diethylamide. The amount of active material in these tissues, moreover, was very small when expressed as equivalent 5-hydroxytryptamine activity, varying from less than 0·5 to 2·0 μgm./gm. freeze-dried tissue. We were also unable to identify 5-hydroxytryptamine by paper chromatography of alcohol extracts from these two species.

The high concentration of 5-hydroxytryptamine in the tissues of the coelenteric cavity of *Calliactis parasitica* is in contrast with its absence in the related species of anemones. A similar situation exists in Octopoda, where the salivary gland of *Octopus vulgaris* contains approximately 500 μgm./gm. 5-hydroxytryptamine, whereas that of *Octopus macropus* contains none[1]. It is also of interest, in view of the presence of 5-hydroxytryptamine in various animal venoms, that the tentacles of *Calliactis*, which are organs involved in the trapping and paralysis of prey, contained the lowest concentration of the tissues studied. It is extremely difficult, therefore, to draw conclusions about any general biological significance of 5-hydroxytryptamine from what is known at present of its seemingly haphazard distribution in Nature.

Vitamin B_{12} and the Metabolism of Pyridine Nucleotides

UNCOUPLING of oxidative phosphorylation in mitochondria from steatotic livers[1] and in experimental thyrotoxicosis[2] is known to be accompanied, among other changes, by a decrease in liver pyridine nucleotides which are of major importance in phosphate uptake during electron transport to molecular oxygen[3]. The pronounced lowering of liver and its mitochondrial vitamin B_{12} in hyperthyroidism[4] as well as in carbon tetrachloride injury (unpublished results), together with the observed protection by the vitamin against both these stress conditions[4,5], would point to a function for the vitamin in the maintenance of tissue-levels of pyridine nucleotides. This has now been ascertained by following the effect in mice of simple vitamin B_{12} deficiency induced by feeding on a high vegetable protein diet[6] on the extent of incorporation *in vivo* of administered nicotinamide into liver pyridine nucleotides in a manner similar to that studied by Kaplan *et al.*[7], and the changes in liver pyridine nucleotides, 6 and 48 hr. after carbon tetrachloride injection to adult rats as described before[5], without and with vitamin B_{12} protection. Total and oxidized pyridine nucleotides were determined fluorimetrically by the procedure outlined by Dianzani[1].

Table 2. PYRIDINE NUCLEOTIDES IN EXPERIMENTAL LIVER INJURY

	Hr. after CCl_4 injection	PN μgm/gm. fresh weight of liver	PN + PNH μgm/gm. fresh weight of liver	PN/PNH
Untreated control	—	667 ± 23	881 ± 21	3 11
CCl_4 injected	6	362 ± 11	595 ± 21	1 55
	48	166 ± 24	278 ± 15	1·48
Vitamin B_{12}-protected and CCl_4-injected	6	489 ± 21	712 ± 28	2 30
	48	387 ± 18	550 ± 15	2·37

PN, oxidized pyridine nucleotides; PNH, reduced pyridine nucleotides.

Adult male rats, 150 gm. weight, fed on the laboratory stock diet (ref. 5) were killed 6 and 48 hr. after intraperitoneal administration of 0·3 c.c. each of CCl_4. Vitamin B_{12}-protected animals received intraperitoneally 10 μgm. each of the vitamin 3 hr. prior to CCl_4 injection. Results are averages for four animals in each case.

It may be seen (Table 1) that the incorporation of nicotinamide into liver pyridine nucleotides, which reaches a maximum level in 8 hr.[7], is less in vitamin B_{12} deficiency, which is also shown by a decrease in the proportion of the oxidized to the reduced pyridine nucleotides. A similar effect due to the vitamin is also observable in the experiments on protection against carbon tetrachloride toxicity (Table 2); it is of interest to note that even though maximum accumulation of liver lipids occurs only after 48 hr. of carbon tetrachloride injection, basic and predisposing metabolic derangements such as reduction in glutathione levels[5] and altered pyridine nucleotide ratios become manifest even after 6 hr.

A decrease in pyridino-protein-linked oxidations[9] and an increase in the proportion of reduced pyridine nucleotides in fatty livers[1] has been noted by others. This condition may be expected to provoke predomination of fatty acid synthesis as compared to breakdown. It has been suggested that vitamin B_{12} may be necessary for the synthesis of the porphyrin-containing proteins of the cell[10] which, apart from

Table 1. VITAMIN B_{12} DEFICIENCY AND SYNTHESIS *in vivo* OF PYRIDINE NUCLEOTIDES

Hours after nicotinamide injection	Vitamin B_{12} deficient			Vitamin B_{12} fed		
	PN μgm./gm. fresh wt. of liver	PN + PNH μgm./gm. fresh wt. of liver	PN/PNH	PN μgm./gm. fresh wt. of liver	PN + PNH μgm./gm. fresh wt. of liver	PN/PNH
0	219 ± 20	357 ± 10	1·58	387 ± 15	525 ± 14	2·78

16	685 ± 25	1,294 ± 24	2·57	1,087 ± 21	1,357 ± 28	4 02
24	293 ± 20	585 ± 19	1·68	447 ± 10	607 ± 19	2 91

PN, oxidized pyridine nucleotides; PNH, reduced pyridine nucleotides.

Adult young male mice, 30 gm weight, were reared on a vegetable protein diet consisting of (in percentages) defatted peanut meal, 46; corn starch, 46; salts IV (U.S.P.), 2; sesame oil (containing 1,000 I.U. vitamin A and 50 mgm. α-tocopherol/gm.), 4·5; cystine, 0·3; choline chloride, 0·2; and vitamin mixture in sucrose, 1. The vitamin supplements provided (in mgm./kgm. of diet): thiamine hydrogen chloride, 5; riboflavin, 5; niacinamide, 10; calcium pantothenate, 20; pyridoxine hydrogen chloride, 2·5; biotin, 0·1; inositol, 100; folic acid, 0 2, and vitamin K, 10. Control animals were fed the same diet with 200 μgm. vitamin B_{12}/kgm of diet. The animals were used at the end of 8 weeks when livers from the deficient and control mice analysed respectively to 55 and 216 mμgm./gm. fresh weight of vitamin B_{12} as assayed with *Euglena gracilis* (ref. 8) Nicotinamide (20 mgm./mouse) was given intraperitoneally and the animals killed at the stated intervals for determinations of liver PN and PN + PNH. Results are averages for four independent samples.

their function as respiratory carriers, are apparently also of importance in determining mitochondrial morphology[11] necessary for oxidative phosphorylation[6] and hence for pyridino-nucleotide metabolism.

Clearing Action of Lysolecithin on Brain Homogenates

In the course of investigations into the metabolism of phospholipids by nervous tissue, it was observed that lysolecithin had a very marked clearing action on aqueous homogenates of whole rat brain. The hæmolytic action of this compound has been studied fairly extensively (see Collier[1]), and its effects on isolated liver mitochondria have also recently been investigated (Nygaard, Dianzani and Bahr[2]), but there appear to be no reports of its action on suspensions of whole tissues.

Lecithin was prepared from eggs by the method of Rhodes and Lea[3], and lysolecithin was prepared from this by that of Long and Penny[4]. Homogenates of fresh whole rat brain and emulsions of lysolecithin were prepared in 0·025 *M* sodium bicarbonate (*p*H 8·3) in all-glass Potter–Elvehjem homogenizers.

The changes in optical transmission of the brain homogenate after the addition of lysolecithin were followed in a Spekker absorptiometer in 2·5 mm. cells using *H*.508 neutral grey filters (Fig. 1).

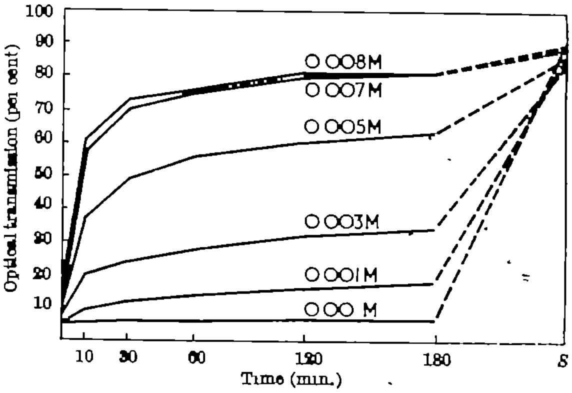

Fig. 1. Effect of concentration of lysolecithin on the rate and degree of clearing of brain homogenates in 0·025 *M* sodium bicarbonate (*p*H 8·3).
All tubes contained 150 mgm. fresh rat brain/3 ml. and were incubated at 38° C. with shaking. *S* represents the optical transmission of supernatant fluids after centrifuging. 100 per cent represents the optical transmission of distilled water

There was an initial rapid increase in optical transmission during the first 10 min., followed by a more gradual rise, over a period of 2 hr., to a maximum value. The final degree of clearing produced in 3 hr. increased with increasing concentrations of lysolecithin and reached a limiting value of about 80 per cent of the optical transmission of water with 0·007–0·008 *M* lysolecithin. At the end of the experiment the contents of all tubes were centrifuged for 60 min. at 21,000*g* at 0° C., and the optical transmission of the supernatant fluids measured. Since only a relatively slight increase in transmission was found following this procedure in the tubes containing the higher concentrations of lysolecithin, it is evident that in these tubes nearly all the brain tissue has been rendered soluble.

The mechanism of this clearing action of lysolecithin on brain homogenates is obscure. Gorter and Hermans[5] found that a given amount of lysolecithin hæmolysed a fixed number of erythrocytes under their specified conditions; and they further concluded that, following lysis, the lysolecithin remained attached to the erythrocyte membrane, since, for a given amount of lysolecithin, the percentage hæmolysis reached a limiting value in about 15 min., and did not increase progressively with time. It seems from Fig. 1 that there is a similar relationship between the amount of lysolecithin present in the system and the maximum degree of clearing produced in a brain homogenate. The amount of lysolecithin required for hæmolysis was found by Gorter and Hermans[5] to be related to the surface area and by Collier and Chen[6] to the cholesterol content of erythrocytes. Whether there is also a similar relation between cholesterol content or some other property of nervous tissue and the amount of lysolecithin needed for clearing a brain homogenate has not yet been determined, but the present results and those of Nygaard *et al.*[2] suggest that it may have some action not only on cell membranes but also on nuclear and mitochondrial membranes.

Although the influence of temperature and of *p*H have not yet been studied in detail, preliminary experiments suggest that clearing of brain homogenates is slower at room temperature than at 38° C., and slower at *p*H 6·4 than at *p*H 8·3.

The ability of a number of other substances to cause clearing of rat brain homogenates was also tested. Using 1 per cent solutions of these substances, under the conditions described in Fig. 1, the final percentage optical transmissions found were: sodium oleate, 52 per cent; sodium deoxycholate, 70 per cent; sodium taurocholate, 26 per cent; saponin, 17 per cent; 'Lubrol W' (cetyl alcohol-polyoxyethylene condensate: Imperial Chemical Industries, Ltd.), 52 per cent (brain only, 7·0 per cent; water, 100 per cent). On the other hand, the optical transmission of homogenates was raised to more than 80 per cent of that of water by only 0·4 per cent lysolecithin.

Lysolecithin also has a marked clearing action on homogenates of liver, kidney and muscle.

This effect of lysolecithin may be of value in enzymic studies on homogenates of tissues, especially of nervous tissue where, owing to the presence of organized lipid-rich myelin sheaths, access of substrates or inhibitors to enzymes may be impeded. The question also arises whether an abnormal production of lysophosphatides, with a consequent disturbance of the physical state of the myelin sheath, could be a factor in the pathogenesis of demyelinating disease. Morrison and Zamecnik[7], in discussing the effects of cobra venom, suggested that lysophosphatides might be myelinolytic, although they made no direct studies of the effects of these compounds on nervous tissue.

I am grateful to Prof. R. H. S. Thompson for his interest in this work, and to Dr. C. Long for a gift of dried snake venom and advice on the preparation of lysolecithin.

Relation between the Ultimate Upper Lethal Temperature and the Temperature-range for Good Health in the Roach (*Rutilus rutilus*)

The ultimate upper lethal temperature for roach, as defined by Fry[1], is 33·5° C. These fish remain in good condition and all survive at 26° C. (for at least three months). At 30° C. roach lose condition and individuals die after a few weeks, while at 32° C. their condition deteriorates rapidly and individuals die within a week.

Experiments in which the temperature of the water was raised slowly also demonstrated that exposure to temperatures below the ultimate upper lethal temperature is highly deleterious. In experiments *A*, *B* and *C* (Fig. 1), roach which had been living for at least four weeks at 20° C. were transferred to tanks at 20° C., the temperature of which was raised by 1° C. a day to 30° C. (Other experiments had shown that at this rate of increase of temperature the fish display complete acclimatization.) In *A*, the fish were kept at 30° C. for six weeks and the temperature was then raised by 1° C. a week to 32° C., and then by ½° C. a week. Six fish out of fifteen died while the temperature was still at 30° C., and 50 per cent of the fish had died while the temperature was at 32° C. (in the eighth week). Five fish were still alive when an accident ended the experiment in the eleventh week (temperature, 33·5° C.). In *B* and *C*, the roach spent only one week at 30° C. before the temperature was raised by 1° C. a week to 33° C. (*B*) or 32° C. (*C*), and then by ½° C. a week to 33·5° C., at which temperature the tanks were held until all the fish had died. In experiment *B*, one fish (out of ten) died at 32° C. and the others at 33·5° C.; 50 per cent of the individuals had died before the end of the sixth week. In experiment *C*, one fish (out of nine) died at 30° C. and 50 per cent had died when the temperature was 32·5° C. during the fourth week. Thus, 50 per cent of the fish exposed for six weeks to 30° C. died at 30–32° C., while of fish with a shorter exposure to the harmful temperature of 30° C., 50 per cent survived until the water had reached temperatures of 32·5–33·5° C.

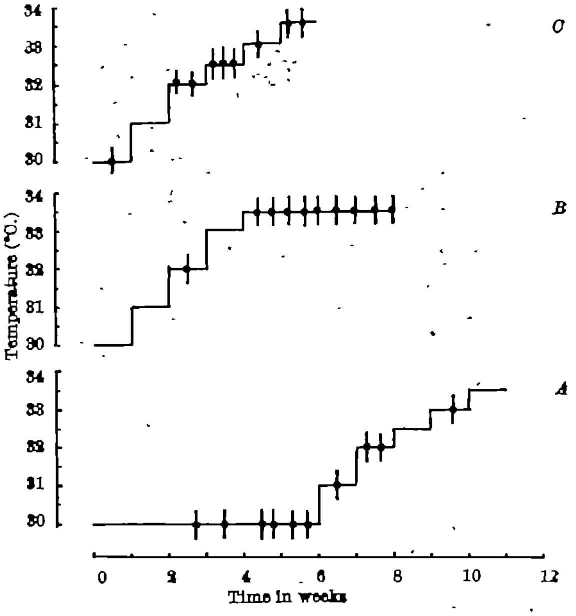

Fig. 1. Diagram showing the time and temperature at which fish died, in three tests, when exposed for a long time to temperatures of 30° C. or above. The stepped line represents the course of temperature change with time in each test. The vertical symbols cutting these lines represent the death times of the fish

The fish were fed five times a week with minced liver but lost weight. Two of the fish in test *C* weighed 23·1 and 9·6 gm. when the experiment started and 11·5 and 5·3 gm. when they died after six weeks.

After prolonged exposures to temperatures between 30° and 34° C., roach become very dark along the back and very thin, so that the spine shows as a pronounced longitudinal ridge. The fish become bow-shaped, no longer swim normally and move with a stiff body by a series of jerky hops. When opened after death, the gall-bladder is large and black.

There is little relation between the ultimate upper lethal temperatures of goldfish, *Carassius auratus*[2], and speckled trout, *Salvelinus fontinalis*[1], and the temperature-ranges for good growth in the two species[3]. The lethal temperature for *Salmo trutta*[4] also bears little relation either to the optimum temperature for good growth at different ages[5] or for development[6].

Long exposures below the ultimate upper lethal temperature, therefore, are harmful to roach and are probably harmful to *Carassius*, *Salvelinus* and *Salmo trutta*. The ultimate upper lethal temperature is a useful index for comparing the thermal relationships of species, but bears little relation to the temperature-range for health and, therefore, breeding. Three important indexes for a species are probably, (*a*) the ultimate upper lethal temperature for the adult fish; (*b*) the temperature-range that will allow satisfactory growth to maturity and spawning; and (*c*) the temperature-range for the satisfactory development of eggs and fry. If the temperature is too high to allow reproduction, a species will disappear from a water although the adult fish are not being killed. The criterion of a suitable maximum temperature for polluted rivers ought to be, therefore, that fish can remain in good condition and breed at that temperature, and not that the temperature is not sufficiently high to kill the fish outright. The present limits for the temperature of polluted rivers may, therefore, be too high.

These results are from work done in the Department of Zoology, King's College, London, while holding a British Celanese Postgraduate Studentship.

Chromosomes of the Potato Root Eelworm

The systematics of the cyst-forming eelworms of the genus *Heterodera* are difficult, and in several cases distinctions between species depend largely on the host-range of the eelworms. In the taxonomy of the higher plants, chromosome numbers have often been useful in determining the limits of species and the relations between species in difficult groups. It was therefore thought that an investigation of the chromosomes of *Heterodera* species might be valuable. Details are given below of a technique that can be used for determining the chromosome number of the potato root eelworm, *Heterodera rostochiensis* Woll.

Females of *Heterodera rostochiensis* were examined at all stages from the time of their first emergence from the root, when they were white and flask-shaped, until they were much larger and spherical, with bright yellow cyst walls, and contained about a hundred eggs in egg cases. All came from potato seedlings infected in plant pots in the greenhouse from soil collected at Feltwell Fen, Norfolk. They were fixed in acetic-alcohol (1 : 3) for half an hour and afterwards placed in a drop of 2 per cent orcein in 45 per cent propionic acid on a microscope slide. The cyst walls were removed, and the contents of the cyst squashed under a cover glass.

Cell division was seen in cysts of all ages, principally in the long convoluted ovary, although mitotic divisions occurred elsewhere in other unidentified tissues. Metaphase of mitosis was only seen in side view, and no details of the chromosome complement could be distinguished, for the chromosomes are tightly retained on a hollow equatorial plate. At mitotic anaphase there is no convergence to the poles, the groups separating in parallel lines. Although the individual components of the groups can be seen more clearly than at metaphase, no cell was obtained in which the chromosome number could be counted.

Many phases of meiosis apparently occur together in the long ribbon of ovary, but the only clear stages at which the chromosomes could be examined were first metaphase and first anaphase. Judged by the frequency with which these stages were observed, meiosis takes place most vigorously in yellow cysts which already contain many developing eggs enclosed in membranes. It would seem, therefore, that eggs are still actively produced at this time, possibly to be fertilized by stored sperm.

At first metaphase of meiosis, nine pairs of chromosomes were present (Fig. 1), the complement consisting of three pairs of larger chromosomes and six pairs of smaller ones. However, all the chromosomes are very small, the largest being about 1·2 μ in length at first metaphase, and are at the limits of resolution of most microscopes; thus detailed description is impossible. The partner chromosomes of each bivalent lie side by side, generally with each member of the bivalent orientated towards opposite poles. There was no evidence of undue lagging at anaphase, and anaphase and telophase were quite normal.

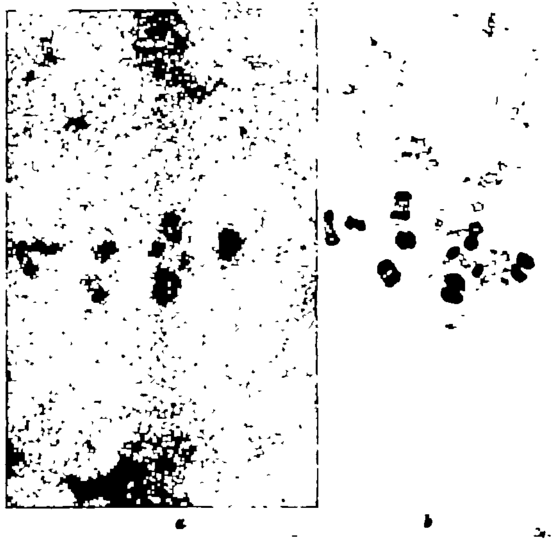

Fig. 1. (*a*) Photomicrograph, (*b*) drawing, of first metaphase of meiosis. × 2,500

This preliminary examination shows that *H. rostochiensis* is cytologically distinct from an unidentified species of *Heterodera* and from a species of a related genus, *Meloidogyne incognita*, both of which have been reported to have 16 chromosomes[1]. Indeed, this evidence of differences in chromosome numbers suggests that cytological studies may be rewarding in defining the limits and relationships of eelworm species.

We acknowledge the ready co-operation of Dr. H. W. Howard in providing infected potato seedlings.

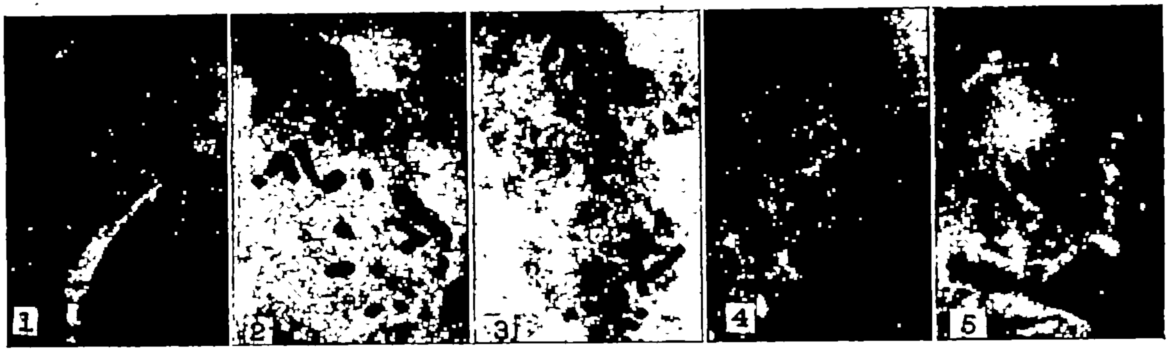
Structural Heterozygosity of *Cipura paludosa*, Aubl.

The genus *Cipura* of the Iridaceae is found in India both in the temperate and tropical regions of the Eastern Himalayas. *Cipura paludosa*, Aubl. is cultivated specially for its dainty white flowers. This species is a native of tropical America and can tolerate varying climates.

The cytology of this species has been studied by us in connexion with the detailed investigation on a number of iridaceous genera undertaken in this laboratory. The chromosome number of this species, as determined from the somatic and meiotic cells, is twelve. The present report deals with the chromosome behaviour of *C. paludosa* Aubl. and the observations show that this species is a structural hybrid.

Extreme stickiness of the chromosomes made the study of their structure by the usual methods of



Figs. 1–5. Mitotic and meiotic chromosomes of *Cipura paludosa*

Figs 1–3. Mitotic metaphase, early metaphase and anaphase, respectively, showing the different morphology of the two large chromosomes (marked with arrow). In Fig. 1 the exaggerated nature of the constriction in one member of the large pair and the centromeric granule in the other member are noticeable

Figs. 4–5. Bivalent configuration of the large chromosomes (marked with arrow) and their separation in anaphase respectively during meiosis. (In Fig 5, the early separation and the difference in size of the members of the large pair is noticeable)

fixation and staining difficult. After a series of trials with different pretreatments, the best result was obtained with pretreatment in a saturated solution of aesculin at 12–14° C. for 30 min. Fixation was then carried out in acetic-alcohol (1 : 1) for 45 min. This step was followed by heating in orcein–hydrochloric acid mixture (2 per cent orcein/*N* hydrochloric acid, 9 : 1) and smearing in 1 per cent aceto-orcein.

The twelve chromosomes of this species can be classified in three distinct categories, namely, four pairs of short chromosomes with median primary constrictions, one pair of medium-sized chromosomes with median primary constrictions and two large chromosomes.

The two large chromosomes are clearly distinguishable from each other (Figs. 1, 2 and 3). One of them is provided with a nearly median primary constriction and a secondary constriction very near the primary one. The other chromosome has the primary constriction located at the sub-median to sub-terminal position. The size difference too is marked, the former being comparatively larger than the latter. The position of the primary constriction is also much pronounced.

The behaviour of these two chromosomes during meiosis is interesting. They remain distinct from the rest of the five bivalents during all the stages of meiosis. They undergo pairing among themselves at the end region, thus forming a heteromorphic bivalent. A ring configuration between these two chromosomes is commonly met with (Fig. 4) even from the early stages of meiosis. During anaphase, this pair undergoes separation earlier than the rest. During this phase, the size difference between the two is quite clear (Fig. 5). Consequently, in the second division also, 50 per cent of the nuclei contain one of the members of the heteromorphic pair and the remaining 50 per cent the other.

The occurrence of a heteromorphic pair of chromosomes is not uncommon in unisexual plants, where these are concerned mainly with the determination of sex. In *C. paludosa*, Aubl., which has bisexual flowers, such chromosomes have no bearing on the determination of sex.

That they are the products of the structural changes of the chromosomes occurring in the evolution of species is apparent. They must have originated through chromosomal changes from a normal homomorphic pair. The pairing behaviour during synapsis of these two chromosomes is significant.

A ring configuration is commonly met with, suggesting homology of the end segments. Such behaviour indicates that the process of structural alternations has mainly affected the intercalary segments of one or of both of them. Pairing at the end region consequently causes no change in the general pattern of the chromosome structure. Intercalary segments, in which the two mainly differ, remain absolutely unaltered. The difference in the intercalary segments has also been brought out clearly in the somatic plates. The morphology of the two differs markedly. Their difference noted both in meiosis and mitosis indicates that a portion of the chromosome segment must have been deleted in one of the members. Further, the early separation during anaphase indicating difference in the timing balance with the rest of the bivalents is possibly the result of structural alterations affecting genes responsible for anaphase movement.

All the individuals collected from the different localities of the plains as well as of the Himalayas are characterized by this heteromorphic pair of bivalents. As no homozygote has yet been obtained, it appears that homozygosity in relation to any of these chromosomes is possibly lethal to the species; some mechanism is undoubtedly operating in Nature to maintain the structural heterozygosity of the species. *Cipura paludosa*, Aubl., therefore, should be classed as a balanced, structural heterozygote.

Effect of the Afforestation of Catchment Areas upon Water Yield

It has recently been argued[1] that the afforestation of catchment areas in Great Britain seriously reduces water yield, and because of this the planting of such areas should cease until it can be proved that the nation's water supplies are not being threatened. In both this paper[1] and a contemporary review[2] the effect has been interpreted primarily as that of afforestation upon transpiration.

It may be of value, therefore, to present certain existing data, from a detailed study[3] of natural and afforested *Calluna* moor in the Cleveland (Yorkshire) massif, which enable this important problem to be seen in fuller perspective.

Soil water determinations, carried out throughout the season upon naturally structured soil clods[4], have shown the podzol profile (0–50 cm.) of undisturbed *Calluna* moor to possess a stable field-capacity. In winter, excess water following rain showers left the moor within two to three days, largely either by draining laterally above the poorly permeable thin iron-pan or as surface run-off. For summers of potential soil-water deficits, calculated from climatic data[5], not exceeding 6 cm. of water, actual deficits in the profile were lower by 10–15 per cent, and for summers of potential deficits as great as 12 cm. this discrepancy rose to 20–25 per cent, or the equivalent of about 2·7 cm. of water. This suggested falling-off in actual transpiration was not unexpected from the fact that more than 80 per cent of the *Calluna* root system was concentrated in a 13-cm. thick surface soil zone, the raw humus and upper bleached horizons, which contained only about 7 cm. available ($< pF\ 4{\cdot}2$) water at field-capacity.

Some twenty-five years growth of *Picea sitchensis* on this site slightly reduced the field-capacity water content of the profile, but for summers of potential deficit of up to 12 cm. of water, actual deficits, measured from the new field-capacity, were no less. The absence of decline in transpiration in this case appeared due to the deeper rooting of the trees. The reserves of available water in the rooting zone were greater and water was withdrawn less exclusively from the surface horizons; hence the chances of attaining conditions of water deficiency were less. Through its effect upon transpiration, therefore, afforestation could, in certain years, reduce catchment yield by up to 3 cm. of water.

Two reasons, however, suggested such a loss to be of no practical importance. First, dry summers are rare in Great Britain: over the representative 32-year period 1921–52, there were only four summers when the potential deficit reached 12 cm. of water and twelve when it reached 9 cm. Secondly, winter rainfall is considerable: for the twelve winters following these summers, from the establishment of field-capacity in autumn until its cessation in spring, the rainfall averaged 52 cm. and never amounted to less than 28 cm. Only a minor fraction of this winter rainfall could be transpired; hence the remainder available for catchment purposes was still large compared with the 3 cm. loss.

But the other main way whereby afforestation might threaten water yield must not be overlooked. Structural changes may be brought about within the soil profile favouring the deep seepage of water, with possible loss to a reservoir, at the expense of run-off. Thus, both the deep forestry ploughing which precedes planting and the tree roots themselves extensively shatter and soften the iron-pan of the natural *Calluna* moor. Deep seepage through the more permeable underlying fragmented sandstone is increased, so that under closed canopy forest, run-off —over either the soil surface or the iron-pan—is no longer commonly seen. Divergence between the topographic and phreatic boundaries of drainage basins becomes a factor of special significance, and a study of the geological structure of the region shows that upon certain catchments increased percolation could result in watershed leakage and reduction in water yield.

Consideration of the effect of afforestation upon water yield, therefore, must embrace all hydrological characteristics of the catchment area. Generalization is difficult, but existing evidence scarcely suggests that upon the impermeable primary rocks of the areas of higher rainfall in north and west Britain afforestation threatens water supplies. The same cannot be said for south-east England, although extensive afforestation of catchments here is rarely a possible form of land utilization. The particular need for research appears to be upon the permeable strata of the north and west.

Permeability and the Size Distribution of Pores

MANY attempts have been made to find a relation between permeability and other measurable properties of porous materials such as particle-size and porosity. The Kozeny equation, which depends on surface area of particles and porosity, has come into rather general use in fields concerned with flow of water, oil and gases and a considerable literature has developed around it[1]. Its weaknesses are that it is unsuited to material having a wide range of pore-sizes, and that it makes use of an empirical factor which departs seriously from its accepted value in consolidated materials. Attention has also been given to the possibility of using pore-size instead of particle-properties, and Childs and Collis George[2] have developed a permeability equation on this basis. An empirical factor is involved and this has not been widely tested for constancy in different materials.

The following equation expresses the permeability of a porous material solely in terms of the size-distribution of its pores. If $r_1, r_2 \ldots$ and r_n cm. represent the mean radius of the pores (in decreasing order of size) in each of n equal fractions of the total pore space, then permeability is given by:

$$K = \varepsilon^2 n^{-2}\,[r_1^2 + 3r_2^2 + 5r_3^2 + \ldots + (2n-1)r_n^2]/8$$

where ε is the porosity in cm.^{3}/cm.^{3} of porous material, and K is in units of cm.^{2}.

In the derivation of this equation, an expression is found as follows for a mean area of cross-section of the necks connecting pores in isotropic porous material. Unit area of surface exposed by a section through such material is considered as being made up of n portions each of the same area, $1/n$, and porosity, ε cm.^{3}/cm.^{3}, and each containing pores of one radius $r_1, r_2, \ldots r_n$ cm., where $r_1 > r_2 > \ldots > r_n$. When that portion of one surface (A) which has pores of radius r_1 makes random contact with the randomly distributed pores of the other surface (B) exposed by the section, it will in effect be in contact with n portions of equal area, $1/n^2$, each containing pores of one size $r_1, r_2, \ldots r_n$ respectively. The area of contact of two pores in the opposite faces will be that of the smaller pore when the contact is perfect, but in the average case it will be ε times the area

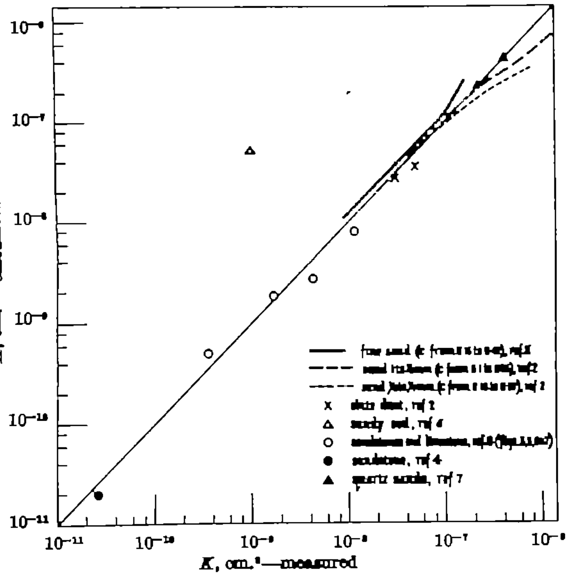

Fig. 1. Comparison of measured permeability with permeability calculated from the size-distribution of pores

of the smaller pore. Hence the resulting neck areas for each of these n portions of surface B will be respectively $\epsilon\pi r_1^2, \epsilon\pi r_1^2, \dots \epsilon\pi r_1^2$. Similarly, that portion of surface A which contains pores of radius r_2 will have neck areas of $\epsilon\pi r_1^2, \epsilon\pi r_2^2, \epsilon\pi r_2^2, \dots \epsilon\pi r_2^2$ respectively for each of the n portions of surface B with which it makes contact. If this process is continued through to that portion of surface A containing pores of radius r_n, a mean neck area can be obtained for the n^2 portions. It is given by:

$$\epsilon\pi n^{-2}\,[r_1^2 + 3r_2^2 + 5r_3^2 + \dots + (2n-1)r_n^2]$$

If this is taken to be the cross-sectional area of a tube controlling flow through the porous material, then, with the aid of Poiseuille's and Darcy's equations for flow through capillary tubes and porous materials respectively, the new equation can be obtained. The assumptions made in deriving this equation are rather similar to those made by Childs and Collis-George[2]. Full details will be published elsewhere.

Measured and calculated permeabilities are compared in Fig. 1 using published data for the permeability and size-distribution of pores of various isotropic, non-swelling materials. These include consolidated[3,4] as well as unconsolidated materials[2,5-7] and those with a wide range of pore-size[3] as well as those with a narrow range[5]. Systems in which either air[3,4] or water[2,5-7] is the fluid and also a three-phase system in which water flows through the unsaturated material[2,5] are represented. In the unsaturated materials the conducting pores are those that are filled with water, so that in such cases ϵ is replaced by c, the volume concentration (c.c. water/c.c. porous material). The results obtained on any one material at different water-contents are given as a curve. In Fig. 1, a range of permeability is represented in which the greatest is more than 30,000 times the least. The fit of the data to the equation is such that the ratio of the larger to the smaller of the values obtained by calculation and by measurement is less than 2·3 in all except one case.

This equation appears to have greater generality than the Kozeny equation. It requires reliable data on size-distribution of pores, and this may affect its use in swelling materials where the usual suction methods for measuring size-distribution may be inaccurate.

Effect of Oxygen on the Carrier Life-time in Silicon

It has been shown[1] that the infra-red absorption band found in silicon at 9μ can be correlated with the oxygen content of the silicon, and that this band is related to the Si—O stretching vibration.

This absorption band has since been used as a sensitive monitor of the oxygen content of silicon crystals pulled in this laboratory. The observed fall-off in oxygen content across a slice cut perpendicular to the direction of crystal growth shows that crystals pulled in a vacuum lose oxygen by evaporation. On the other hand, crystals pulled in an atmosphere of argon plus water vapour show an increase in oxygen content near the surface. This is thought to throw some light on the mechanism whereby boron can be removed from silicon[2].

Results obtained recently, given in Table 1 and Fig. 1, point to correlation between the oxygen content and the carrier life-time, τ. It is found that the presence of oxygen increases τ. At first sight this is unexpected, as it is usual to consider that any departure from crystal perfection will reduce the carrier life-time. An exception is the case of traps which have been observed in silicon[3]. These have, however, been eliminated from the present experiments by means of a suitable ambient illumination. The explanation is thought to be that there is some

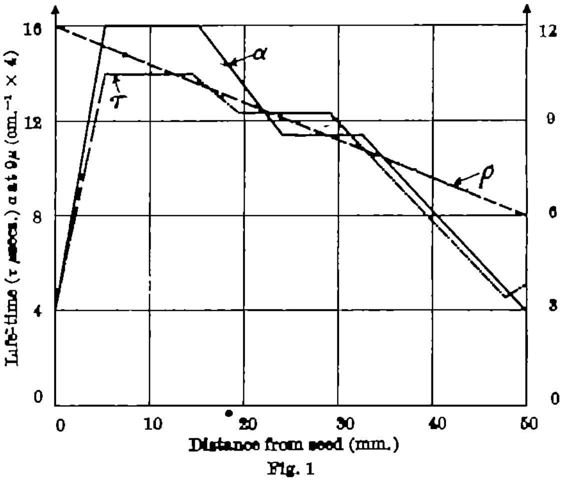

Fig. 1

Table 1

Crystal No.	Atmosphere during growth	α (cm.$^{-1}$)	τ (μsec)
177	Vacuum 2×10^{-4} mm.	1·1	2
181	Vacuum 8×10^{-4} mm.	1·25	10
166	Vacuum 3×10^{-5} mm.	1·5	12
148	Vacuum 5×10^{-5} mm.	1·75	13
150	Argon and water vapour	6·0	20

recombination centre X which can either be nullified by chemical interaction with the oxygen or which competes with oxygen for a place in the lattice. The nature of X is not known at present, but it is suggested that X might be an interstitial silicon atom, frozen into the lattice during the crystal-growing process[4].

Kaiser[5] has shown recently that a suitable heat treatment can lead to the production of donor centres the distribution of which along the crystal can be correlated with the amount of oxygen present. It is intended to extend the present work to an investigation into the relationship between heat-treatment effects, life-time, oxygen content and dislocation density. A more complete account of the experimental techniques and results will be given elsewhere.

In the present results, the value of the absorption coefficient, α, in cm.$^{-1}$ at 9μ is taken as a measure of the oxygen content. In the calculation of α, background absorption due to free carriers has been allowed for, because of its dependence on resistivity.

Boron in the Glasshouse Tomato Plant

DATA concerning the boron content of the glasshouse tomato plant were required in connexion with an investigation of a fruit condition known as 'bronzing'. Negligible information on this subject is to be found in the standard references[1-3]. The boron contents of the tomato plant presented in the following tables may, therefore, prove useful in future diagnostic work.

In the pot experiment three rooting media were employed: (1) silver sand; (2) compost No. 1 prepared from a local steamed soil; (3) compost No. 2 prepared from a glasshouse soil, where 'bronzing' has been a problem, and two tomato varieties—Anti-mold *A* and Ailsa Craig. One series of three pots per variety was irrigated with a complete nutrient solution containing 2 p.p.m. of boron and an identical series with a nutrient solution minus boron (except for 'starter' doses of the solution containing boron given to the silver-sand pots). All treatments were replicated twice. Boron was determined colorimetrically in the laboratory on the fruit and associated leaves, all determinations being carried out in duplicate. A summary of the results is given in Table 1.

Table 1. POT EXPERIMENT 1956: GLASSHOUSE TOMATO PLANTS
(Boron expressed as p.p.m. on a dry matter basis)

Sampling month and stage of growth	Leaf analysis			Fruit analysis		
	Complete nutrients	Minus boron S.S	Minus boron C.	Complete nutrients	Minus boron S.S	Minus boron C.
July 1st truss ripening	82	26	48	14	3	8
Early August 2nd and 3rd trusses ripening	41	16	33	8	4	8
Late August 4th and 5th trusses ripening	18	5	14	5	No fruit	4

S.S., Silver sand; C, compost

Typical boron deficiency symptoms[2,3] were observed only in the tomato plants grown in silver sand and irrigated with 'minus boron' nutrient solution. Both the composts were able to supply sufficient boron to their plants.

Table 2 presents the boron contents for samples taken from tomato plants on various commercial nurseries in the north of England over the period 1954–56.

Table 2. ANALYSES OF HERBAGE SAMPLES TAKEN FROM TOMATO PLANTS ON VARIOUS COMMERCIAL NURSERIES, 1954–56
(Boron in parts per million on a dry matter basis)

Month of sampling	Leaves	No of samples	Fruit	No. of samples
June	55	18	14	20
July	58	19	14	19
August	22	4	8	8

Three points of interest emerge from this work.

(1) Boron deficiency is unlikely to be of economic importance in the tomato plant. This confirms the conclusion of independent investigations[3,4].

(2) The values presented in certain standard references are high compared with those obtained in this investigation. Goodall and Gregory[1], quoting work undertaken by Eaton[4] in the United States, abstracts the following values:

Boron in p.p.m. (on a dry matter basis) in plants *not* showing symptoms of boron deficiency

Period	Leaves	Fruit	Plant
July–August	34–150	24–27	29–78

Wallace[3] gives a value of 46 p.p.m. boron for healthy tomato leaves, which compares favourably with the values in the above tables.

(3) Boron contents decrease markedly as the season progresses.

The assistance of the field and laboratory staff of the Chemistry Department, National Agricultural Advisory Service, Newcastle upon Tyne, is gratefully acknowledged.

FORTHCOMING EVENTS

(*Meeting marked with an asterisk * is open to the public*)

Tuesday, October 1

University College, London (in the Physiology Theatre, Gower Street, London, W.C.1), at 5 p.m. Prof. M. Heidelberger (U.S.A.): "The Chemistry of Proteins and Carbohydrates in Relation to Immunological Specificity" *

Society of Chemical Industry, Plastics and Polymer Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. H. W. Russell: "Plastics in the Aircraft Industry"

Wednesday, October 2

Institute of Petroleum (at 26 Portland Place, London, W.1), at 5.30 p.m.—Dr. H. Powell and Mr. W. H. Thomas: "Modern Trends in Petroleum Analysis", Mr. S. W. J. Wallis and Mr. D. S. Townend: "New Trends in the Instrumentation of Refinery Processes"

Society for Analytical Chemistry (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Scientific Papers.

Thursday, October 3

Ross Institute Industrial Advisory Committee (in the Council Chamber of the Rubber Growers' Association, 19 Fenchurch Street, London, E.C.3), at 2.15 p.m.—Dr. O. J. S. Macdonald: "Present Day Health Problems on Plantations (with Special Reference to Housing)".

Physical Society, Low Temperature Group (in the Lecture Theatre of the Royal School of Mines, Prince Consort Road, South Kensington, London, S.W.7), at 4 p.m.—Dr. R. Berman and Dr. A. H. Cooke: "Reports of the Fourth U.S.S.R. Low Temperature Meeting, Moscow, July 1957".

Royal Society of Medicine, United Services Section (at 1 Wimpole Street, London, W.1), at 5 p.m.—Wing-Cmdr. P. F. King and Flight Lieut. P. Gannon: "The Problem of Noise in the Royal Air Force"

Institute of Metals, London Local Section (at 17 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. H. C. Rhodes: "Fourteen Elements".

Royal Society of Medicine, Neurology Section (at 1 Wimpole Street, London, W.1), at 8 p.m.—Dr. W. Ritchie Russell: "Physiology of Memory"

Thursday, October 3—Friday, October 4

Society of Chemical Industry, Food Group, and the Association of Public Analysts (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1)—Symposium on "The Quality Control of Food"

Friday, October 4

Plastics Institute (at the Borough Polytechnic, Borough Road, London, S.E.1), at 2.30 p.m.—Sir Miles Thomas: "Challenge of Plastics to the Arts and Technology"

Society of Dyers and Colourists, London Section (joint meeting with the London Branch of the Clothing Institute, at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Mr. N. J. Read: "Flame-proofing of Textile Fabrics, with particular reference to the Function of Antimony Compounds".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Experimental Officer (preferably with a pass degree in science or laboratory experience in biochemistry, biophysics, or immunology, or at least G.C.E. in five subjects (mathematics or science) at advanced level or equivalent) in the Experimental Pathology Department, to work on electrophoresis—The Secretary, The Institute of Animal Physiology, Babraham, Cambridge (October 5).

Demonstrator in Horticultural Science (for mycology and plant pathology)—The Registrar, The University, Bristol 8 (October 5).

Research Assistant (with a degree in agriculture or agricultural botany and some experience in plot techniques) in the Department of Botany—The Deputy Registrar, The University, Birmingham 15 (October 5).

Assistant Lecturer in the Department of Biochemistry and Chemistry—The Secretary, Royal Free Hospital School of Medicine (University of London), Hunter Street, London, W.C.1 (October 9).

Scientific Officer (with a first- or second-class honours degree in chemistry) in the Department of Spectrochemistry, for duties which will include investigations involving various aspects of infra-red and ultra-violet absorption spectroscopy—The Secretary, Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen (October 12).

Senior Lecturer or Lecturer (with a first- or second-class honours degree in physics) in Physics at the Royal Military College of Science, Shrivenham, Berkshire, for teaching at university level—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A 26/77A (October 12).

Advisory Officer (with a good degree in engineering, preferably with postgraduate experience in dairy engineering, or a degree in science or dairying with extensive subsequent experience in dairy engineering) in Dairy Engineering—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (October 15).

Assistant Lecturer or Lecturer in Physical and Inorganic Chemistry—The Secretary and Registrar, University College of North Wales, Bangor, North Wales (October 18).

Senior Technician in Zoology at University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (October 25).

Lecturer or Senior Lecturer in Botany at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, October 31).

Lecturer (preferably with qualifications and experience in X-ray techniques or geochemistry) in the Department of Geology and Mineralogy, University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, October 31).

Lecturer (preferably with qualifications in applied mathematics) in Mathematics at the University of Tasmania, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, October 31).

Lecturer (university graduate in civil engineering and preferably with some professional experience) in Civil Engineering at Auckland University College (University of New Zealand)—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, October 31).

Lecturer (honours graduate in chemical engineering, physical chemistry or mechanical engineering) in Chemical Engineering—The Deputy Registrar, The University, Birmingham (November 1).

Scientific Officer (with a good honours degree) in the Virology Section of the Plant Pathology Department—The Secretary, Scottish Horticultural Research Institute, Mylnefield, Invergowrie, by Dundee (November 2).

Wellcome Research Fellow (with a good honours degree and research experience) in Zoology at the University College of Rhodesia and Nyasaland, to collaborate with Prof. E. B. Edney in work on sensory physiology of tsetse flies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (November 10).

Chair of Chemistry in the University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (November 15).

Lecturer in Applied Mathematics—The Registrar, University of Adelaide, Adelaide, South Australia (November 15).

Lecturer in Social Anthropology at Auckland University College (University of New Zealand)—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, November 15).

Assistant Editor (with either (*a*) a good knowledge of languages, including Russian, and some acquaintance with chemical terminology, or (*b*) a good knowledge of physics or chemistry or mineralogy, and some acquaintance with European languages) of *Structure Reports*—Prof. A. J. C. Wilson, University College, Cardiff.

Assistant, Grade B (with a good honours degree and preferably some previous teaching experience), for Mathematics—The Clerk to the Governors, Mid-Essex Technical College and School of Art, Market Road, Chelmsford.

Assistant Physicist (with an honours degree in physics) in the Radiotherapy Department, Royal South Hants Hospital, Southampton, to assist on radium and X-ray problems, including rotational therapy, as well as radio-isotope work—The Secretary, Southampton Group Hospital Management Committee, Bullar Street, Southampton.

Demonstrator (honours graduate in botany with an interest in mycology, plant pathology or microbiology) in Horticultural Science—The Registrar, The University, Bristol 8.

Electronics Technician (preferably with experience in the radio frequency power generation of pulse systems) in the Nuclear Engineering Laboratory, for work which includes the development and construction of instrumentation for thermonuclear research—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1.

Head (with research and teaching experience) of the Physics Department (Grade IV)—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11.

Head (highly qualified in chemistry and with some experience as a full-time lecturer in a technical college or university, and the ability to initiate and develop chemical research) of the Chemistry and Metallurgy Department (Grade III), Coventry Technical College—The Director of Education, New Council Offices, Coventry.

Graduate Physicists and/or Mechanical Engineers in the Fuel Technology Section of the Plant Engineering Division of the Association in London, for research work concerned with the application and economic use in the iron and steel industry of all forms of energy—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting "F.T.1".

Lecturer/Demonstrator in the Chemistry Department—The Bursar, Royal Agricultural College, Cirencester.

Lecturer in Physical Chemistry in the Department of Chemistry and Biology—The Principal, Kingston Technical College, Fassett Road, Kingston-on-Thames.

Research Assistant (young graduate in physiology or a related science)—Dr. A. Elithorn, Neurological Research Unit (Medical Research Council), National Hospital for Nervous Diseases, Queen Square, London, W.C.1.

Research Worker in the Department of Industrial Metallurgy, for work on the frictional and surface properties of titanium and its alloys during metal-working processes—The Deputy Registrar, The University, Edgbaston, Birmingham 15.

Senior Research Assistant (with a Ph.D. in physics and preferably several years additional research experience in solid state or magnetic resonance problems) in Physics, for a research programme on paramagnetic resonance in semiconductors—The Registrar, King's College, Newcastle-upon-Tyne.

REPORTS and other PUBLICATIONS

EXPERIMENTS IN BIOCHEMICAL RESEARCH TECHNIQUES

by

Robert W. Cowgill & **Arthur B. Pardee**
Department of Biochemistry, University of Colorado — *Department of Biochemistry, University of California*

189 pages Illustrated 28s. net

This book presents advanced experiments illustrating the actual methods used by research workers and will serve as a useful guide to procedures and applications as well as to the key literature of modern biochemical research techniques.

EXPERIMENTAL DESIGNS

by

William G. Cochran & **Gertrude M. Cox**
Professor of Biostatistics, The Johns Hopkins University — *Director, Institute of Statistics, University of North Carolina*

Second Edition 610 pages Illustrated 82s. net

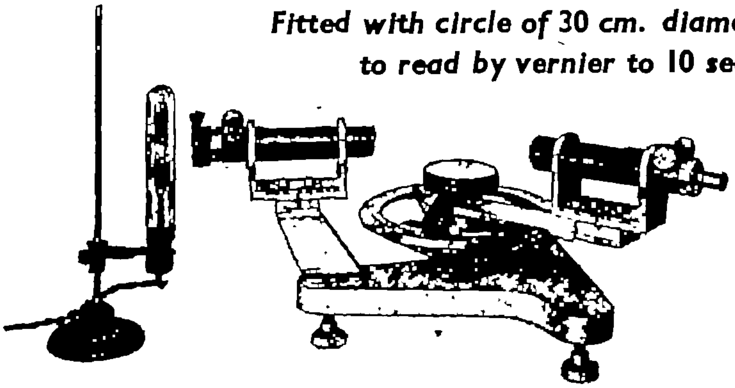
A working manual for research workers in all branches of science. Revised and expanded, it describes the most useful experimental designs, with detailed instructions for their use.

37 ESSEX STREET, LONDON, W.C.2

PRECISION INSTRUMENTS

Spectrometer No. 3

Fitted with circle of 30 cm. diameter divided to read by vernier to 10 seconds



PRISM TABLE rotates and is fitted with levelling screws

TELESCOPE AND COLLIMATOR have centring adjustment

EYEPIECE is of 25 mm. separation

Our technical staff are always available to give help or advice on any of our instruments or their uses.

SOCIAL IMPLICATIONS OF AUTOMATION

A PASSAGE in the report of the Advisory Council for Scientific and Industrial Research for 1955–56 refers to the sponsoring of research into the social and economic implications of automation, and pertaining to the work of the Department in stimulating thought and further studies of the human and psychological element in the partnership between employed, employer and consumer, especially with the view of removing frustrations which hamper good industrial relations. Such studies are at present the responsibility of the Department's Intelligence Division, advised by the Committee on Economics and Industrial Operations set up early last year under the chairmanship of Prof. E. A. G. Robinson; and on the advice of this Committee the Department placed a contract with Political and Economic Planning for a case-study of automation in a large firm. Three such case-studies have recently been published by PEP*, one of which, on the manufacture of bearing tube, was undertaken for the Department of Scientific and Industrial Research.

All three studies were undertaken to obtain impartial and dispassionate close comparisons of methods and operations before and after the introduction of automatic techniques, so as to bring out the technical, economic and managerial consequences of automation and the problems to which it gave rise. The report does not attempt to generalize from the evidence obtained, though it may be said that on the whole it supports the report on automation issued by the Department last year. All three studies bring out the increased importance of planning when more automatic methods are used, both for the introduction of new methods and for more detailed day-to-day guidance of operations when the automatic equipment is in use. They do not, however, indicate that detailed and accurate forecasts of future requirements will be any more available to a firm installing automatic equipment than to other firms. Business forecasting is thus of increasing importance, while the need for more careful planning involves a higher proportion of management and supervisors in the total labour force. The proportion of maintenance workers to operatives also had to be increased, new and higher skills being required to maintain the new equipment.

The most important results and advantages of the automatic methods appear to have been in the realm of technical improvements. In the tube study, more variable sizes and tolerances are affected. It seems inconceivable that the 'Platformer' studied at Stanlow could operate without automatic process control, while some of the greatest advantages of Lyons Electric Office, commonly known as the 'Leo' computer, have been the provision of more information more quickly and accurately. These are results not easily evaluated in economic terms, though they may be more important than the direct financial advantages which can be calculated. The increased productivity arising from the changes was, however, well proved, amounting to something more than 200 per cent in the tube-making case study, while Leo can do the work of 200–400 clerks per shift with a very much smaller number of operators, maintenance engineers and programmers.

The only redundancy discovered in these three studies occurred during the change-over from the old to the new methods, and has not proved a permanent feature; but at the same time it is emphasized that skills have changed and men have had to transfer from one job to another. Re-training has been necessary, but the evidence is that for most of the operating staff this has not presented serious problems. So far as the new maintenance skills are concerned, the difficulty has been to obtain a supply of men with the right qualifications or experience. Training of maintenance workers is an important matter to which much effort has been devoted.

Some of the old manual skills have been eliminated by the use of more automatic methods, and piece-rates have been rendered obsolete; but the evidence does not suggest that the operative has been made more subservient to the machine. The men in the new tube mill need perceptual skills, and while conditions of work have improved it appears also to be true that satisfaction in work has increased. The operators of the Platformer need, too, conceptual skills, and they have to monitor it intelligently. Furthermore, the operators of the tube mill exercise a considerable degree of personal intervention in the process, and must work as a team to get the best results; this new type of team-work, required when automatic methods are used, is probably the most important theme running through these three studies. Management, supervisors, operatives and maintenance engineers appear to become very much part of one team, the members of which must work together if the best is to be obtained from the new machinery; in this there is hope that social gain may accompany economic advance.

The three studies were chosen to be as representative as possible of the different types of automatic production; but Political and Economic Planning emphasizes that no sweeping deductions can be drawn from this evidence, and in particular that the reassuring evidence on redundancy cannot be applied over the whole of industry. Although, for example, the study of Leo indicated that the electronic office has not so far resulted in redundancy, this does not mean that use of electronic computers in industry, commerce and administration will never cause redundancy. This particular computer was chosen for study because it is the computer with the largest history of successful application to routine clerical work in Britain. The manufacture of bearing tube by the Tube Investments Group was chosen as offering a good direct comparison between an old plant still in operation and a new mill, the Assel Elongater, while the Stanlow Platformer was chosen as a good example of modern refinery practice.

---

* Three Case Studies in Automation. Pp. vi+58. (London: Political and Economic Planning, 1957.) 7s. 6d.

One of the most interesting features of these studies is the way in which they underline much of the argument of the Earl of Halsbury, both in his paper last year before the Royal Society of Arts and in those he has since contributed to *Impact*, particularly that on integrating social with technological change. This aspect he considered to some extent in his paper in *Impact* of December 1956, where he emphasized the psychological problems requiring attention, and pointed out that if a man's occupation was transformed by a machine, he should be given the chance to be the man to work the machine if he can; if his skill is rendered redundant by the whole complex of action by managements, designers, technologists, scientists and others, those actions should include re-establishing him at his old earning power, and the cost of doing so should be part of the true cost of the technical development rendering him redundant. Lord Halsbury recognized the danger of industrial society becoming divided into two hostile sub-groups—a managerial group relatively free and a worker's group relatively bound, and that it is essential to accumulate dispassionately the facts which could give manager and worker an objective picture of one another and promote goodwill and trust.

In a more recent paper, in the March issue of *Impact*, Lord Halsbury analyses more particularly the antagonism between these two groups, which, he suggests, should be the first concern of industrial psychology. Four sets of explanations are required: (*a*) of the worker to the manager; (*b*) of the worker to himself; (*c*) of the manager to the worker; and (*d*) of the manager to himself. But so far study has been concentrated on the worker with the view of giving the manager an authoritative picture of the worker's needs. The findings in this context have already been largely adopted in practice by the best employers, and further concentration on this aspect is unlikely to be rewarding; though Lord Halsbury stresses the courage and tact required to investigate the mentality of the employer and to get the worker to see himself objectively.

This is a programme for long-range fundamental research, nor can it be certain that the knowledge when won will be applicable. Meanwhile, every effort should be made to raise conditions of employment generally to the level of the best, and Lord Halsbury points out that managers should recognize that the failure of friendly efforts to remove distrust or aggressiveness may well be due to this gap in our knowledge. Again, empirical efforts to promote freedom at work should be more thoroughly explored, and technical progress should be watched for signs of anything that may alleviate environmental conditions. Above all, he insists we must be ready to introduce corrective factors in unforeseen situations before those situations deteriorate. The trend towards automation, for example, must increase general synchronism between one worker and another, and it would thus be possible to displace stresses arising from the monotony of the sub-divided repetitive task and the assembly line on to maintenance engineers responsible for the upkeep of the transfer line and the automatic assembly units. Probably every solution in this field is a compromise, but intelligent anticipation at least offers a choice between the better and the worse.

Whether or not the Department of Scientific and Industrial Research is the appropriate focus to which the organization for research in Britain on these studies of the human aspects of automation should be brought is a large question; and although the National Institute of Industrial Psychology has now taken its place among the institutions which receive grant under the research association scheme, the question should not be regarded as settled. It is, of course, not easy to draw a sharp distinction between the more mechanical aspects of productivity and the human aspects of such problems; but the argument for a social and economic research council seems somewhat stronger than when the proposal was advanced more than ten years ago.

The very different approach to problems of automation and productivity which marks an article by Mr. S. B. Bailey in the *Westminster Bank Review* of August seems to point in the same direction. Mr. Bailey is concerned particularly with some lessons we might learn from the United States regarding productivity and incentives. He points out that with a smaller population, lower wages, higher selling prices and purchase tax, the demand in Britain for many mass-produced goods is much less than one-tenth of what it is in the United States. Accordingly, with smaller production quantities, it would not be economic to mechanize production methods to the extent common in the United States; but without such automation we cannot hope to equal American productivity and thus attain her standard of living. The wages of the British worker could be doubled or trebled, he suggests, if his productivity equalled that of the American worker; but as the case studies of automation confirm, the necessary equipment could only be economically installed if run to capacity, for example, on double shifts, and it would also be essential for the worker to abandon restrictive practices and co-operate fully to take advantage of the new methods.

Mr. Bailey is highly critical of retail trade in Britain, in which, he suggests, we have made ourselves a nation of price-fixers in contrast to a robust nation of keen buyers and shopkeepers in the United States, and also of taxation policy in Britain, particularly purchase tax. Our economic troubles he considers arise largely from lack of competition and incentives, and the European Free Trade Area may give British manufacturers the spur they need; and if traders were freed from re-sale price control there would be an additional powerful stimulus to efficiency. He insists that while the benefits of the welfare State are attracting to the shores of Britain the unskilled who can just earn their own keep, our taxation policy is driving away the highly skilled and creative worker whose efforts create employment for thousands. He does not agree with the view of the Overseas Migration Board in its second report, that the rate of loss of professional engineers does not give cause for alarm, and argues that we cannot afford to export to North America more than 10 per cent of our annual increment in professional and mechanical engineers.

Lord Halsbury entitled one of his papers "Automation—Verbal Fiction, Psychological Reality"; and this group of studies and papers is to be welcomed as a contribution to the realistic thinking needed if the potentialities of automation for productivity and for economic and social advance are to be realized. They indicate clearly the openmindedness and adaptability which will be required at all levels, from that of the Government downward, and the wide implications of the whole process, as well as the large field for social and economic research. It is perhaps above all as a contribution to the immense task of education which must proceed with, and to some extent precede, the introduction of automatic methods that they are most welcome. While they are not specially addressed to the scientist, he will find in them much to encourage the application of scientific method and ways of thought to problems that are technical as well as economic and social.

EVOLUTION AND THEOLOGY

Evolutionary Theory and Christian Belief

The Unresolved Conflict. By Dr. David Lack. Pp. 128. (London: Methuen and Co., Ltd., 1957.) 10s. 6d. net.

THIS must be as impartial a book as has ever been written on a highly controversial problem. It is notable in addition for the exhaustive knowledge which its author shows of the relevant literature both past and present, and one is agreeably surprised to discover that, even when the battle between evolutionists and religious spokesmen was at its fiercest, there were thinkers on both sides who were able to distinguish between the real and the spurious issues, and to keep both their heads and their tempers. Dr. Lack shows an admirable restraint in refusing to decide issues when the evidence is insufficient, and, if at the end he leaves open the question of the relation between evolutionary theory and Christian belief, from the point of view of the scientist, it is with the explicit recognition that biology provides as little positive support for scientific humanism as for Christianity. On two points only he commits himself definitely: first, that natural selection is able to account for the main features of evolutionary change, and secondly, that evolutionary theories of ethics are inadequate. The latter conclusion is reached, it should be noted, on philosophical rather than scientific grounds, and it may be added that Dr. Lack is more competent than many distinguished scientists have been in handling philosophical arguments.

No sensible theologian will want to build the temple of religion on the shifting sands of contemporary science, but it is worth remarking that the traditional Christian account of man's origin and predicament seems to be far more compatible with modern biology than are the outlooks of so-called liberal Christianity. The doctrine that sin began in a pre-human realm, with the fall of angelic beings one of whose functions was the supervision of the material world, was not elaborated in order to explain why the universe was disorganized before the appearance of man, a fact which at the time was unsuspected; it is therefore all the more impressive that it performs this function. Again, while evolution makes it practically impossible for us to hold that bodily death in general was the consequence of man's fall, it offers no obstacle to the view that, in Dr. Lack's words, "if the Fall had not occurred, man's physical nature was to be miraculously changed, so that he was to become immortal and no longer subject to biological limitations" (p. 79); and it is this, and not the view that man was *naturally* immortal, that is the traditional doctrine of Christian theology. Even if we may regret the present Pope's denunciation of polygenism, we must admit that most contemporary anthropologists would agree with him on this point. However, I have dealt with these questions more fully elsewhere, in my "Christian Theology and Natural Science".

Finally, we may raise the question whether evolution by natural selection is any less congenial to Christianity than are views which hold the universe to be penetrated by some kind of entelechy or *élan*. We are told that there are in the universe something like 100 million galaxies, each containing something like 100,000 million stars, many of which no doubt are accompanied by planets forming possible sites for the appearance of living beings. Furthermore, when we examine the only one of these sites with which we have direct acquaintance, we see that the main line of evolution, that which leads up to man, has threaded its way through innumerable points of bifurcation, at each of which the side road was fated to run into a dead end of over-specialization or inadequate adaptability. In this gigantic universe man, for all his presumed uniqueness, thus appears as one of those occasional oddities, like the yarborough at cards, which are bound to turn up occasionally if you set going a sufficiently enormous number of random processes; as in fact the product of chance rather than of design. Suppose, however, that God uses just this method of 'chance' in order to produce here and there the occasional physical organism which, by its organic adaptability and its cerebral complexity, is an adequate counterpart for a rational and spiritual soul. Admittedly, this method will seem outrageously wasteful to the economical mind of bourgeois man, who will expect a God to whom all things are possible to reach His ends in a simpler and tidier way. However, a Being whose resources are unlimited has no need to be governed by considerations of economics, and He will in any event be glorified by the 'dead ends'—the dinosaurs and ants and bacteria—as well as by the beings into which He has infused a rational soul. Perhaps some modern theologians have gone badly wrong in looking for evidences of large-scale design in the universe. The truth may be that God is great enough to be able to achieve His ends without that kind of design; it is at least significant that 'cosmic teleology' is a modern feature of Christian apologetics which is not found, for example, in St. Thomas Aquinas.

This book is of much greater importance than its size would suggest. It would provide admirable material for group-discussion on all levels of philosophical competence.

E. L. MASCALL

HIGH POLYMERS

Textbook of Polymer Chemistry

By Fred. W. Billmeyer, Jr. Pp. viii + 518. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 10.50 dollars.

Polymer Processes

Chemical Technology of Plastics, Resins, Rubbers, Adhesives and Fibres. Edited by Calvin E. Schildknecht. (High Polymers: a Series of Monographs on the Chemistry, Physics and Technology of High Polymeric Substances, Vol. 10.) Pp. xvii + 914. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1956.) 19.50 dollars.

Chemistry of High Polymer Degradation Processes

By Dr. Norman Grassie. Pp. xv + 335. (London: Butterworths Scientific Publications; New York: Interscience Publishers, Inc., 1956.) 42s.

The Chemistry of Phenolic Resins

The Formation, Structure, and Reactions of Phenolic Resins and Related Products. By Robert W. Martin. Pp. xi + 298. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1956.) 76s. net.

THE unique properties which high polymers possess and which distinguish them from other substances are associated with the concept that the polymer molecule is built up of a structure very many times greater than those occurring in simple substances. Although this viewpoint—which did not receive acceptance until the 1930's—had a profound influence on the development of polymer research, it was not until the 1940's that suitable methods were developed for the full quantitative study of the relationships between polymer properties and constitution. The immense technological development which has followed from these discoveries has had a tremendous impact on our daily lives and the chemical and engineering industries. All but a few of the wide variety of synthetic polymers now in use have been developed during the past two decades. The beginnings of the plastics industry, however, go back long before the establishment of the principles of synthesis. Vulcanized rubber was commercialized one hundred years ago, and cellulose derivatives and the phenol formaldehyde resins were developed industrially in the early part of this century.

The field of polymer science and the progress in polymer technology is still growing very rapidly and the books under review cover various aspects of the chemistry of polymeric substances.

Dr. F. W. Billmeyer's text-book summarizes and classifies the more interesting and important information about the organic and physical chemistry of high polymers. It is written for graduate-level students who desire to specialize in this subject. The fifty-seven relatively short chapters may be divided broadly into four parts: physical chemistry of high polymers (1–18); kinetics of polymerization (19–31); plastics (32–43); and fibres and elastomers (44–57). Although the basic principles are formulated in a clear and elegant manner, the author seems to attempt too much, in that, in addition to a fundamental theoretical treatment, the properties of the main types of plastic, rubbers and fibres, together with the short descriptive account of polymer processing and other technological procedures, are summarized. For those who prefer the theory and practice in one volume the book fills this need. It is certainly one of the best general text-books yet produced.

"Polymer Processes" is written by an outstanding group of authors, all having long experience in their respective fields. The book deals with the chemical aspects of polymer technology and especially the newer processes of the preparation, formulation and shaping of plastics, rubbers, fibres and adhesives. The earlier chapters deal with the important methods of laboratory and plant processes by which olefinic monomers are polymerized, namely, bulk suspension, emulsion and solution. The next chapters summarize in detail the preparation and properties of the polyamides and polyesters, cellulose and cellulose derivatives—epoxy resins, polysulphide polymers, new adhesives, condensation with formaldehyde. The remaining section of the book deals with recent advances in the chemical technology of polymers, namely, paste and latex techniques, compounding and processing of rubbers and resins, polymer reinforcement and spinning and drawing of fibres. The book bridges a gap between theory and practice, and throughout the various chapters recent developments of both theoretical and practical interest are emphasized. The editor, Dr. C. E. Schildknecht, who himself contributes three excellent chapters, has succeeded in demonstrating the contribution of theory to technical advance.

The degradation of high polymers is of interest for two reasons. On one hand controlled degradation is of technical importance in the processing of polymeric materials, as in the milling of rubber or the hydrolysis of polysaccharides. On the other hand, a knowledge of the conditions and mechanism of degradation is of importance technically, as it determines the surface behaviour of the polymer and the limiting conditions under which it can be fabricated. A study of these processes has led to the introduction of more useful types of polymers and the development of methods of stabilization and protection during fabrication. Dr. N. Grassie's book provides an excellent account of our present knowledge of polymer degradation reactions. He discusses not only the types of reactions which occur within the environment of polymer chains but also the elementary reactions which make up the composite change occurring during the degradative reaction. Thus, in separate chapters he describes studies on model compounds such as the oxidation of olefines, sulphurization and ozonization, ester decompositions, etc., which although they cannot be included within the term degradation are of vital importance in elucidating the reactions of rubbers and synthetic fibres. In bringing the facts together in a systematic manner Dr. Grassie has established certain general principles which will be of immense value in the further understanding of this subject.

The phenolics constitute the oldest and most studied group of thermosetting resins, and interest in these materials has steadily grown since the outstanding studies of Baekeland at the beginning of the century. The interest in the technology of the resins during the early days of the phenolic resin industry far overshadowed interest in the chemistry involved or in the pure chemicals that might be obtained by proper control of the reaction conditions. However, as the resin technology developed and the applications of the resins became more specialized it became necessary to know more about the mode of formation, factors which determine resin properties, cure, etc. It is the latter considerations which are dealt with in Dr. R. W. Martin's book. The chemistry of the preparation and structure of the phenol-aldehyde reactions is discussed in detail. Other sections review the chemistry of the cure of phenolic resins, the joint reactions of phenols and aldehydes with an added reagent, the formation of cyclic products and the reactions of the phenol-aldehyde products, and the final chapter summarizes the results obtained from reaction-rate studies. The book presents for the first time under one cover the present-day chemistry of phenolic resins and related products, and although written mainly for the resin chemist the emphasis is always directed to the nature of the chemical process occurring rather than the application. The book is a valuable survey of the subject and will be most useful to resin chemists, technologists and others interested in the wider chemistry of polymers.

C. E. H. BAWN

ECONOMICS OF NUCLEAR ENERGY

The Economics of Nuclear Power including Administration and Law

Edited by J. Guéron, J. A. Lane, I. R. Maxwell and J. R. Menke. (Progress in Nuclear Energy, Series 8.) Vol. 1. Pp. xiii+513. (London: Pergamon Press, Ltd., 1956.) 120s. net.

THIS book, which is one of the series issued by the Pergamon Press on "Progress in Nuclear Energy", is well produced and well printed, and contains a mass of information. The book is divided into five sections, of unequal length. The first section, on the needs and resources of energy, occupies the first third of the book. The next three sections, on nuclear power economics, on nuclear fuel cycles, and on reactor programmes and reactor economic data, occupy the middle third of the book, while the last section on administration and law occupies the remainder of the book, together with an adequate index.

The first part of the book, on energy needs and resources, contains general papers dealing with fuel reserves, rates of growth of power requirements and possible uses of nuclear energy, and in addition there is a selection of papers summarizing the energy position in some countries. The general papers on this subject form a convenient source of reference information on the energy requirements of various countries. Similar information is available in other papers, but it is probably true to say that it is expressed as concisely here as anywhere.

In the middle section of the book, dealing with the economics of nuclear power stations, one gets on to ground which is much less firm. It is here that there is a shortage of facts, and a surfeit of predictions. This, of course, is no fault of the book, but a natural consequence of the newness of the whole field of nuclear power. Not until more information is available from nuclear power stations that have actually operated will it be possible to decide which of the predictions are true, and which are not. The shortage of facts refers not only to the actual cost of reactors, but also to the costs of fabrication of fuel and all the other processes which go to make up the complete nuclear fuel cycle. This question of nuclear fuel cycles is well covered by the papers in the third section of this book.

The last section of the book, on administration and law, brings together a number of papers dealing with the various problems that have arisen, which are specific to the use of atomic energy. The papers given here illustrate the position which has been reached in the various countries actively concerned with the development of atomic energy. It is apparent from these papers that while every attempt is being made to produce codes of practice similar to those used in older and more established industries, this is proving a difficult problem.

Although the majority of the information in this book was given at the Geneva Conference in 1955, it is not for that reason particularly out of date, for whereas much more has been written on the subject since then, there has not been any significant change in the position. The prototypes of some forms of nuclear power reactors have now come, or are now coming into operation, but it is still too early to obtain a comprehensive picture of their true costs, and in any event these first models are prototypes and are not the same as the reactors which will be built for large-scale power generation.

C. A. RENNIE

DISTINGUISHED THERMODYNAMICS

Thermodynamics

An Advanced Treatment for Chemists and Physicists. By Prof. E. A. Guggenheim. Third edition. (Series in Physics.) Pp. xxiii+476. (Amsterdam: North-Holland Publishing Company, 1957.) 34.50 guilders.

THAT a third edition of Prof. E. A. Guggenheim's "Thermodynamics" has appeared barely eight years after publication of the first edition is proof that its unique merit as a comprehensive, logical, and coherent treatise is widely appreciated. The subject is presented as a mathematical system, starting from a few fundamental quantities, one of which is entropy. Entropy and absolute temperature are introduced together, and neither is defined in terms of anything supposedly simpler, for the author does "not admit the existence of any simpler thermodynamic quantities". This approach has logical advantages, but most beginners will need more help than is given here in relating entropy, at any rate, to more familiar physical quantities.

To those who already have some knowledge of thermodynamics, this book will be a treasure house of methods and results, invaluable to chemists particularly, but also to physicists. The topics dealt with include one-component systems, mixtures, including dilute solutions and solutions of electrolytes, chemical reactions, galvanic cells, systems in gravitational, electrostatic, and magnetic fields, and radiation. The treatment of the thermodynamics of surfaces is original and a marked advance on previous treatments.

Naturally much of the material presented has been well known for a long time, but Prof. Guggenheim imparts his own clarity and individual flavour to the argument everywhere; and his comments on commonly used methods and conceptions are always illuminating, often critical, and sometimes pointedly disapproving. He considers the time-honoured practice of using "heat of reaction" to denote the heat given out in a reaction "deplorable"; but many may think that the old sign convention, by which the heat of combustion of coal, or heat of fission of uranium, are large positive quantities, should not be abandoned merely to make the symbol for heat of reaction ΔH instead of $-\Delta H$.

There are several changes since the first edition, mostly in the treatment of solutions. Solutions with many components are discussed along with two-component solutions, instead of in a separate chapter. Prominence is now given to Scatchard's 'excess functions' as an alternative to activity coefficients or an osmotic coefficient, for expressing the deviation from ideality of solutions. The osmotic coefficient φ, used in this edition, is not identical with the osmotic coefficient g used formerly, although it becomes equal to g at great dilution. The author has apparently abandoned the use of an osmotic coefficient except for very dilute solutions, which seems a pity. Following Hildebrand's desire to restrict the term 'regular' solutions to those where the entropy change on mixing is that for ideal solutions, a new term, 'simple' solutions, has been introduced to describe most of those called 'regular' in the earlier edition; and the existence of truly regular solutions, apart from ideal solutions, is now challenged. The rather unexpressive term 'degree of advancement' has been changed to the clearer 'extent of reaction'. There is a new chapter on Onsager's reciprocal relations.

Though the book deals mainly with classical thermodynamics, the results of statistical thermodynamics are frequently used, though often only an outline of the statistical argument is given. The book is thoroughly up to date and authoritative, and the thought-provoking challenges frequently thrown out to customary conceptions and methods which may lack precision are salutary, even though not all the criticisms will necessarily be accepted as valid.

N. K. Adam

DOCUMENTATION AND DISSEMINATION OF INFORMATION

Documentation in Action

By Jesse H. Shera, Allen Kent and James W. Perry. (Based on the 1956 Conference on Documentation, at Western Reserve University.) Pp. xv + 471. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1956.) 80*s*. net.

As the sub-title suggests, this book is based on a symposium on documentation, but the implications of the subject may not be very clear to potential readers, particularly those on the eastern side of the Atlantic. The purpose of the book is to promote the widest possible dissemination of information. The method is to discuss in original articles and programmes existing and envisaged systems and equipment for storing, classifying and correlating recorded material with the view of ensuring its maximum availability and therefore potential value.

As J. H. Shera points out in the introduction, "The world of thought (scholarship) and the world of action have always been interdependent", and this means that to provide for an efficient human society we require to build up an efficient scheme of communications. At the present time with the rapid increase of knowledge, and even more rapid increase of the volume of publications, this need is becoming even more imperative than before. The newly emerging science, dealing with the organization of human knowledge, which has not as yet received a distinctive name, includes a very large number of departmental aspects, such as linguistics, semantics, logics, philosophy, principles of classification, library organization, card systems and recording and calculating machines, organization of scientific societies and scientific and technical publications, abstracting and reviewing services, book production and many other matters. In the words of J. H. Shera: "The new discipline that we here envisage, and which for want of a better name we have called 'social epistemology', will provide a framework for the effective investigation of the whole complex problem of the intellectual processes of society—a study by which society as a whole seeks to achieve a perceptive or understanding relation to the total environment. It will lift the study of intellectual life from that of the individual to an inquiry into the means by which a society, nation, or culture achieves an understanding relationship with the totality of the environment, and its focus will be upon the production, flow, integration, and consumption of all forms of communication throughout the entire social pattern. From such a discipline should emerge a new body of knowledge about, and a new synthesis of the interaction between, knowledge and social activity".

The book consists of a number of original articles as well as discussions and co-operative programmes. Part 1 contains seven articles on documentation terminology, co-operative information processing, logic of research, librarianship, methods of storage and retrieval of information and on the use of information. Part 2 contains programmes for the future on the utilization of recorded knowledge, with six articles on abstracting, librarianship, and the role of language in the communication of recorded information. Part 3 contains seventeen discussions of the subjects raised in the articles. Part 4 contains five co-operative programmes, called 'co-operative information processing', for branches of science dealing with metals, pharmaceuticals, petroleum, documentation as such and patents. Machine translation, programmes of Unesco and mechanisms for flow and retrieval of research information are also discussed.

The choice of terms used in this book ('processing', 'project', 'language engineering' and the verb 'to programme') brings us into close contact with the American vitality of language and action; but this need not deter the scientist, or engineer, or anyone dealing with organized knowledge or administration from studying this book.

The problems it tackles are the outcome of the enormous increase in the rate of production in knowledge and the imperative necessity for utilizing it in the service of human society by developing efficient systems of 'communication'.

S. I. Tomkeieff

Birds of New Guinea

By Tom Iredale. Illustrated with Thirty-Five Plates in Colour, figuring 347 Birds, by Lilian Medland. Vol. 1: Pp. xv+230+plates 1–15. Vol. 2: Pp. xv+261+plates 16–35. Edition limited to 1,500 copies. (An Australiana Society Publication.) (Melbourne: Georgian House, Pty., Ltd., 1956.) 24 guineas the set.

THE great tropical island of New Guinea is remarkable for its ecological diversity. The coral coastlines support a lush strand vegetation that gives way to thick rain forests or occasionally (in the south) to savannah. There are great tracts of upland *kunai* grass-lands, and above these there are moss-forests. Over all tower the New Guinea Alps with their cover of permanent snow. There are, too, large rivers and extensive tracts of mangroves, as well as freshwater sago swamps, wide reed-beds and both coastal and upland lakes. These varied conditions support an extraordinary variety of birds and, in particular, great numbers of parrots, pigeons, kingfishers, cassowaries, megapodes ('incubator-birds'), honey-eaters, bower-birds, birds-of-paradise and other groups that reach their highest development on, or are restricted to, the Australian side of Wallace's Line.

There still remain large areas of New Guinea unvisited by Europeans, although the birds of many relatively accessible districts are rapidly becoming known. Until the appearance of Mr. Iredale's volumes, there was no single, comparatively non-technical, account of the country's avifauna as a whole. Mr. Iredale deals with some 650 species, of which 347 are presented in thirty-five beautiful colour-plates. One volume deals with non-passerine forms, and the other with passerines. The work contains a great deal of absorbing information; and it is unfortunate that it gives only the briefest references to other literature. It will be read with critical interest by systematists concerned with the Australasian region, and should be of high general value (and in particular a useful species identification) for New Guinea Europeans with a feeling for natural history. The production maintains the high technical standards of Georgian House. It is sad that the artist, Lilian Medland (Mrs. Iredale), did not live to see the publication of her exquisite pictures.

A. J. Marshall

An Introduction to Blood-Group Serology

Theory, Techniques, Practical Applications, Apparatus. By Kathleen E. Boorman and Dr. Barbara E. Dodd. Pp. viii+317. (London: J. and A. Churchill, Ltd., 1957.) 40*s*. net.

IN 1940, blood grouping meant typing an individual's blood for ABO groups and perhaps occasionally titrating his serum for the corresponding anti-A and anti-B antibody. The other blood groups known at that time were the M, N and P groups, previously discovered by Landsteiner and Levine, and these tests were carried out in cases of disputed parentage. In 1940, Landsteiner and Wiener discovered the Rh group, and from then on a great change took place. A study of the Rh group showed it to be a complex group that was of considerable clinical significance apart from its importance in blood transfusion therapy, and despite war-time difficulties considerable progress was made in this study both in Britain and the United States during the years following 1940. Additional blood groups have now been discovered so that nine such systems are known. They have been found to be much more complex than was originally thought, and several blood group antibodies recently discovered have detected antigens which are related to one of the previously known blood group systems.

The term 'blood group' implies that an individual has on his own red cells a particular antigen. These react with the corresponding blood group antibodies, and it is the detection of these antigen–antibody reactions that constitutes blood grouping. Prior to 1940, saline agglutination techniques were used, but since 1940 many new techniques have been employed, and but for these the discovery of several blood groups could not have been made and the presence of the corresponding antibody in an individual's serum not suspected. These techniques constitute blood group serology, and it is with these practical matters that this book deals. It describes a large number of methods which are available for this work; the techniques are numbered and many different ones are described, including those recently introduced into general routine work. It is a pity, however, that the authors do not come down more strongly in favour of particular techniques; a large number is available and it is necessary to choose the most desirable in the given circumstances. Nevertheless, the book forms a handy reference book and guide to laboratory methods, which are succinctly described, and it is well suited for the use of laboratory technicians.

F. Stratton

Semiconductor Surface Physics

Proceedings of the Conference on the Physics of Semiconductor Surfaces, held at Philadelphia, Pennsylvania, June 4–6, 1956. Edited by R. H. Kingston, with the assistance of E. Burstein, A. L. McWhorter, P. H. Miller, Jr., D. T. Stevenson, and P. B. Weisz. Pp. xvi+413. (Philadelphia: University of Pennsylvania Press; London: Oxford University Press, 1957.) 68*s*. net.

THE papers read at the Conference on the Physics of Semiconductor Surfaces have been divided, in the book, into four groups: (*a*) clean surfaces; (*b*) real surfaces; (*c*) adsorption and catalysis; (*d*) oxidation. The second group, not surprisingly, occupies as much space as the others put together; the third, mainly devoted to catalysis, is as much chemistry as it is physics.

It is only very recently that surfaces have been obtained sufficiently free of foreign atoms as to warrant the description 'clean', and further examination of their properties is necessary before existing theories can be checked. The real surfaces of germanium have long been studied, particularly in terms of rates of recombination of holes and electrons (or surface recombination velocity), surface conductances, contact potential and photo effects. Models of the surface, of both germanium and silicon, include 'fast' states, sited at the interface between an oxide layer and the bulk material and responsible for capture times of less than 1 μsec., and 'slow' states. The 'slow' states are probably sited on the surface of the oxide layer, have properties which are very dependent on surface treatment and the ambient atmosphere, have long capture times and are responsible for excess noise with an energy spectrum inversely proportional to frequency. The last of the four sections of the book is introduced by a summary of the oxidation of metals and includes a description of experiments on the action of oxygen on clean germanium surfaces and a theoretical discussion. The outcome of some of the work described could be of overwhelming importance in improving the initial performance, the consistency and the reliability of transistors.

There are some gaps in the subject as presented, and some contrasts in presentation; but generally the book is very readable and is recommended to everyone studying the physics of semiconductors or the technology of transistors or semiconductor diodes.

J. R. Tillman

Quantitative Chemical Analysis

By Prof. Robert B. Fischer. Pp. xii+401. (Philadelphia and London: W. B. Saunders Company, 1956.) 38*s.* 6*d.*

THE author, a professor in the University of Indiana, is acutely aware that many a student whom he instructs in analysis will never use it in his career, and that those who become industrial chemists are more likely to meet a kind of analysis—instrumental—other than that learned at the university. Accordingly, Prof. R. Fischer has framed his course to meet this condition of things. His guiding principle seems to be to inculcate scientific thinking and so make the study and practice of analysis a training in research. Of the book's five parts the first consists of a well-planned and well-written introduction. Parts 2 and 3 deal with a selection of standard gravimetric and volumetric methods such as are usually found in first-year university courses. Part 4 is intended to be an introduction to instrumental analysis. It contains a description of optical and electric methods, but gives laboratory procedures for simple colorimetry and electrodeposition only. Part 5 consists of tables, including one of five-place logarithms. Ninety illustrations, including highly magnified electron micrographs of familiar precipitates, add to the interest of the subject-matter.

Throughout the book the treatment is thorough. Several of the chapters, such as the one on precipitation, and that dealing with analytical data, are, as it were, self-contained scholarly reviews of the subjects in question. Before any determination is undertaken the student is trained to seek out and study the fundamental chemistry involved, and to select the most appropriate techniques. Serious students mastering this book will get a good grounding in the theory and practice of quantitative analysis and will not find it a dull subject.

G. Fowles

Volumetric Analysis

By G. Fowles. Revised and enlarged edition. Pp. xiii+235. (London: G. Bell and Sons, Ltd., 1957.) 12*s.* 6*d.* net.

IN this edition the framework of the original text has not been altered, apart from the occasional rewriting of explanatory matter, such as that on *p*H and redox indicators. Two new chapters have been added, one on 'complexing processes' and the other on ceric sulphate as an oxidizing agent. In addition, forty-six numerical problems with answers have been added, together with a table of logarithms. The simple account of 'complexing processes' is very satisfactory, apart from the misleading statement that a bromide will not give a precipitate with the solution obtained by dissolving silver oxide in aqueous ammonia. Many teachers will welcome the clear exposition of Schwarzenbach's method for the determination of the hardness of water by the use of the sodium salt of ethylenediamine tetracetic acid—the name is much more frightening than the formula or the method of using it. The use of standard solutions of ceric sulphate is discussed and illustrated by a number of examples. As the author rightly points out, cerium is not a rare element, and ceric sulphate possesses many advantages over potassium permanganate as a reagent in volumetric analysis. The first edition of this book provided for an obvious need—it was reprinted five times—so that this volume with its useful additions should have a favourable reception.

A. C. Cavell

Thought, Life and Time as Reflected in Science and Poetry

By Dr. H. C. Wood. (Tenth Arthur Stanley Eddington Memorial Lecture, 19 February, 1957.) Pp. vi+58. (Cambridge: At the University Press, 1957.) 4*s.* 6*d.* net.

THIS, the tenth Eddington Memorial Lecture, is a worthy member of the series, and of note in that the author approaches his difficult task along the paths of history and theology. This route is, in the event, not so roundabout as it might appear. Eddington himself regarded natural science as a means of reaching one of the frontiers of human knowledge, beyond which other concepts, poetical, metaphysical or religious, had to take charge if the totality of our apprehension was to be achieved. One result of this was that Eddington wrote such beautiful prose (a lesson indeed to many a scientist) that occasionally he invited criticism for ambiguity. But the gain was greater than the loss: the æsthetic quality of his analysis was a direct challenge to the near-identity of truth and beauty.

For the rest, it seems unlikely that mankind has been vouchsafed something at least akin to a spark of the Divine if his desire to know ultimate truth is to remain for ever unsatisfied. We have yet to be convinced that a robot can be constructed to which it *matters* that, if it thinks, its thoughts are true.

Finally, the university must never lose or take lightly its emphasis upon intellectual imagination, and all that such a privilege implies. Following Eddington's footprints on the sands of time, it should be secure.

F. I. G. Rawlins

Seven Pond Creatures. Seven Birds. Seven Trees. Seven Animals

15 pp. each. By Edna Johnson. (Oxford: Basil Blackwell, 1957.) 2*s.* each.

MANY writers have attempted to deepen the interest of young children in living creatures. In a well-known series Enid Blyton used her imaginative gifts to prepare delightful fairy-like stories based on authenticated fact; the series was wholly successful. Other writers have prepared factually accurate accounts which have been less successful because they took insufficient note of the romantic quality of the child-mind. In this series Edna Johnson uses brightly coloured illustrations by Anyon Cook to attract attention and then adds to the interest by text which has been meticulously prepared and which has all the appeal of simple blank verse. It should commend itself to most young children. The text is precise, accurate, sparing of words and supplemented both by homely black-and-white drawings and by photographs from well-known bird photographers. The drawings are worthy of the coloured illustrations and the text; some of the photographs are badly reproduced and do not add to attraction or understanding.

THE LARGE-SCALE STRUCTURE OF THE GALAXY

By F. J. KERR, J. V. HINDMAN and MARTHA STAHR CARPENTER*

Commonwealth Scientific and Industrial Research Organization, Radiophysics Laboratory, Sydney, Australia

OPTICAL studies of the structure of our galaxy are restricted to the immediate neighbourhood of the Sun, because the light from distant stars in the galactic disk is heavily attenuated by interstellar dust. Radio waves, on the other hand, can penetrate the dust, and the whole of the galaxy is accessible to radio investigations, provided the wave-length is not too long.

The most powerful of the radio methods for studying large-scale galactic structure is based on observations of the line from interstellar hydrogen at a wave-length of 21 cm. In this case the possibility of measuring radial velocities provides a means of distinguishing, to a large extent, between radiation from sources at different distances along the same line of sight. In these observations, the hydrogen is used as a tracer, to delineate the spiral arms and the thin galactic disk in which the gas is largely concentrated. The spiral pattern for the northern part of the Milky Way, as derived from hydrogen line observations by the Leyden Observatory group, is now well known[1], but only a few preliminary results have so far been published for the southern part[2].

In this communication we extend the spiral picture, through the addition of more comprehensive southern observations. We also present a 'relief map' of the galaxy, which shows the major departures of the hydrogen layer from a plane, and briefly discuss the overall distribution of the hydrogen.

The southern survey has been carried out with an aerial of diameter 36 ft. (beam-width 1·5°), and a receiver band-width of 40 kc./s. (equivalent to a velocity spread of 8·5 km./sec.). A strip of sky around the Milky Way, about 8° wide in galactic latitude, has been covered in a series of sweeps, usually 5° apart in longitude. The southern half of the Milky Way has received the main attention, but some observations have also been made in the northern longitudes which are visible from Sydney. A fixed-frequency stationary-aerial system has been used, allowing the Milky Way to drift across through the aerial beam. Simultaneous observations were made on four separate receiving channels.

The analysis is now sufficiently advanced to show the main structure and shape of the galaxy quite clearly, although some parts of the observational material have still to be reduced. No allowance has yet been made for the finite resolving power of the instrument, or the random motions of the interstellar gas clouds, but the broad conclusions presented here should not be significantly changed. The detailed results of the study will be published later.

Spiral Structure

A composite picture of the spiral pattern in the galactic disk is given in Fig. 1, with the new Sydney results to the left, and the latest spiral diagram from Leyden[3] to the right.

The individual observational points are shown for the Sydney diagram only. The positions of the various concentrations of hydrogen which can be seen in each line of sight are indicated by filled circles; these are associated with the various peaks on each line profile. A series of small open circles corresponds to a broad peak on a profile, which

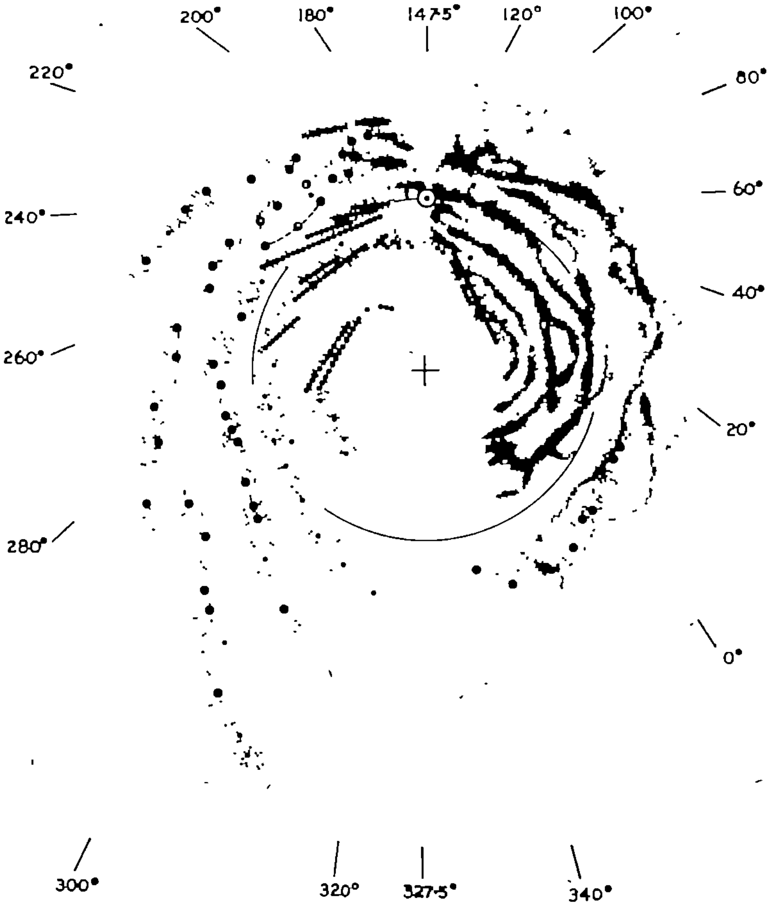

Fig. 1. Composite spiral diagram of the galaxy. The Sydney pattern is to the left of the picture, the Leyden one (slightly retouched) to the right, with some overlap. The different character of the two sides results from different methods of analysis and representation. The distance from the Sun (⊙) to the galactic centre (+) is taken as 8·2 kiloparsecs.

---

* Now returned to Cornell University, Ithaca, N.Y.

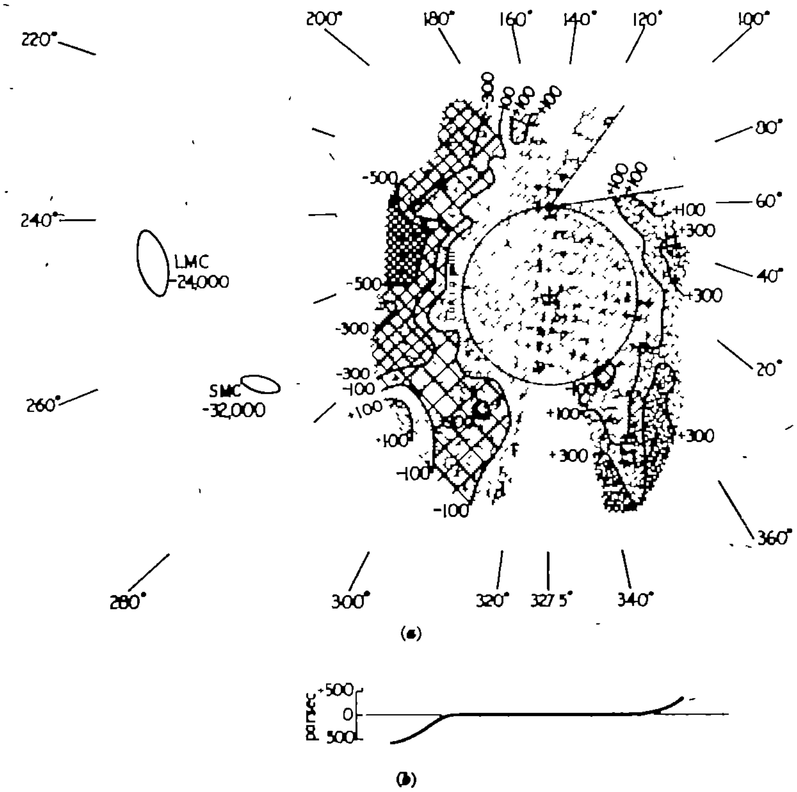

Fig. 2 (a) Relief map of the galaxy, showing departures of the equatorial surface of the hydrogen from an approximation to the 'principal plane'. The contour levels are in parsecs. (b) Cross-section through galactic centre, in the direction of Large Magellanic Cloud

presumably indicates a spiral arm seen end-on. The array of points has been joined up to give a schematic representation of the spiral pattern. No attempt has been made to indicate variations of density along the arms.

Distances have been derived from the radial velocities of the peaks, in terms of the rotational velocity model which was used by van de Hulst, Muller and Oort[1], assuming that the gas is everywhere moving in circular orbits. This method of deriving distance fails in sectors towards the galactic centre and anticentre.

The Sydney part of the diagram has been left blank within 2 kiloparsecs of the Sun, where it is difficult to distinguish between radial velocities associated with the spiral pattern and the peculiar velocities of very close gas clouds. Also, the structure is incompletely presented in the region closer to the galactic centre than the Sun, where there are two alternative distances for each radial velocity. These can be distinguished to some extent by measuring the angular width in galactic latitude, but this information has not yet been completely analysed for the Sydney results.

The Leyden picture completes the diagram in the northern longitudes which are not accessible from Sydney or have received less attention in our observations. The Sydney and Leyden line profiles agree quite well in the regions where the observations overlap, though the use of different equipment parameters has led to differences in detail. The agreement in the positions of the spiral arms is less good, because the two sets of results have been worked out with slightly different velocity models. In view of the fluid state of such models at present, it was thought unnecessary to bring the two parts to the same basis, by recomputing one or other of them.

The different appearance of the two parts of the diagram results from the different approaches which have been used. The Sydney diagram is a schematic representation, and is based only on the well-defined features of the line profiles. The Leyden picture, on the other hand, is an 'artist's impression', following the contours of highest gas density, and it has also taken account of the finer and less-certain details of the profiles.

Our own observations do suggest, however, that there are significant differences in the hydrogen distribution on the two sides of the galaxy. In the outer regions, the peaks in the spiral arms are less pronounced on the southern side than they are in the northern sector. This implies that the gas is less well organized into spiral arms in southern longitudes, with something of a continuum of gas between the arms. Also the wings of the profiles (on the side corresponding to the outer regions of the galaxy) extend much farther out in southern longitudes.

Three major conclusions can be drawn from this spiral diagram: (i) The galaxy has a multi-armed structure. (ii) The arms show a general trailing tendency. (The direction of rotation in this diagram is clockwise.) (iii) There are shortcomings in currently used rotational velocity models. (This follows from the rather 'heliocentric' form of the derived pattern.)

Reading outwards from the centre on the southern side, the so-called Scutum-Norma[4], Sagittarius, Orion and Perseus arms can each be followed over a wide range of galactic longitude. There are suggestions, in fact, that the major arms can be followed through two or more revolutions, but this cannot be established from the present results.

The arms seem to be clearly trailing, but the exaggerated degree of trail near longitudes 300°–320° is probably a result of the model which was used. A different distribution of rotational velocity with distance is apparently needed; but there is in addition a large quantity of gas in this and other regions which cannot be fitted to any reasonable model which is limited to circular orbits. There is no evidence, however, for a general deviation from circular motion of the type suggested by Edmondson[5]. The velocity pattern is found to be asymmetrical about the galactic centre, in the region between 3 and 7 kiloparsecs from the centre, but the evidence suggests that this is due primarily to structural asymmetries, rather than to wholesale departures from circular motion.

The Galactic Plane and its Distortion

We consider now the disposition of the gas in a direction normal to the galactic plane. Each sweep across the plane at a given longitude and frequency gives the 'vertical' distribution of the neutral hydrogen at a particular place in the galaxy. In particular, the galactic latitude at which peak brightness occurs gives a point on the 'equatorial surface' of the layer of neutral hydrogen.

Thus we can delineate a section through the galaxy for each line of sight; the observations give the variation of galactic latitude with radial velocity, from which we can derive a curve showing the height of the equatorial surface as a function of the distance.

The hydrogen is confined to a thin layer (about 250 parsecs between half-density points) in the galactic disk, and observations of this type provide the best method for a new determination of the galactic plane, the position of which is under review by the International Astronomical Union.

A relief map of the galaxy, built up from the Sydney observations, is shown in Fig. 2*a*. This picture is based on the same velocity model as the spiral diagram, and again it has been drawn without making allowance for random motions; but the main features should not be changed by later modifications.

The gas layer is found to be remarkably flat in the inner parts of the galaxy. We have called the mean plane in this region the 'principal plane of the galaxy'. (This plane does not necessarily pass through the Sun.) For the present purpose, we have used an approximation to the principal plane as the reference level in Fig. 2. This approximation is a plane which contains the Sun, and slopes downwards from the conventional 'galactic plane' at an angle of 1·5° towards the galactic centre at longitude 327·5°.

In the outer regions, the gas layer shows a systematic distortion, with a twist downwards on the left of the picture and upwards on the right. The effect can be seen more clearly in the cross-section of the galaxy given in Fig. 2*b*. The distortion appears to be a large-scale property of the galaxy, as the height of the gas layer varies fairly regularly, with little relationship to the pattern of spiral arms. This effect has also been noticed by Burke[6].

The downward deviation is greatest in the region nearest the Magellanic Clouds, which are below the plane in the position indicated; the upward deviation is greatest on the opposite side. The phenomenon suggests a gravitational tide produced by the Clouds, but the effect appears to be about two orders of magnitude too large for a simple gravitational explanation. There may be an analogy with cases reported by Zwicky[7] and others, which imply unexpectedly large interactions between galaxies.

The interpretation is less clear in the far wing of the line profile, beyond the region of the spiral arm peaks, where the intensity is very low. Here there is often a reversal in the curve of galactic latitude against radial velocity, from which the relation between height and distance is derived. This might be taken to indicate that the deviation of the equatorial surface from the principal plane decreases again beyond the region shown in the diagram. However, the reversal is associated with an increase in the angular width, and sometimes occurs at velocities which are too great to be fitted to a circular orbit model. Our interpretation is that the radiating gas in this case is relatively close to the Sun, and moving in non-circular orbits.

As well as giving the shape of the hydrogen concentrations, these observations can provide the point-by-point density distribution of neutral hydrogen throughout the galaxy. The detailed distribution has not yet been fully worked out for the southern observations, but we have derived provisional results for the overall amount of neutral hydrogen in the galactic disk, and its mean radial distribution[8]. These have been compared with corresponding figures for the total mass given by Schmidt's recent model[9].

The ratio of neutral hydrogen to the total mass increases on going outwards from the centre; it rises from a very low value in the nucleus to about 15 per cent at the Sun's distance, and 50 per cent at 14 kiloparsecs out. The gas is a major constituent in the outer regions, but the proportion of neutral hydrogen integrated over the whole galaxy is only about 2 per cent.

BIOGENESIS OF NATURAL PRODUCTS

A SYMPOSIUM on "Biogenesis of Natural Products", arranged by Section B (Chemistry) of the British Association and held on September 6 in Dublin, was introduced by the president of the Section, Dr. J. W. Cook, who began by remarking on the appropriateness of the choice of Sir Robert Robinson as chairman. He recalled that Prof. J. N. Collie, of University College, London, himself a pioneer in the field, when introducing his successor, Prof. Robinson, remarked that his sort of chemistry was 'real' organic chemistry. This remark is even more recognizably true to-day.

Sir Robert opened his consideration of "Biogenesis of Structural Relations: the Organic Chemist's Contribution" by pointing out how organic chemists' interests in natural products have changed from being an interest purely in structures to one concerned with the origins of such structures. His own pioneer work in the alkaloid field in 1917 indicated that structural relations do, in fact, reveal something of origins, although he realized that the final word is always with the biochemist. Recent powerful techniques such as the use of compounds containing isotopic carbon (carbon-14) have enabled the biochemist to test the predictions of the organic chemists. Their speculations have proved in some cases incorrect, but were correct in a surprisingly large number of cases.

He considered briefly the origins of fatty acids with an *even* number of carbon atoms from acetic acid units (containing two carbon atoms) and some of the other distinguishable biogenetic groups: the *iso*pentane compounds (terpenes, steroids), the C_6—C_3—C_6 groups and others.

Sir Robert's main thesis concerned the structural relations of alkaloids. The parallel series of pyrrolidine (five-membered ring) alkaloids, derived from the amino-acid ornithine, and the piperidine (six-membered ring) alkaloids derived from the amino-acid lysine containing an extra carbon atom, had originally led to biogenetic theories since confirmed by tracer studies. The whole series of compounds of the *iso*quinoline series can be correlated on the basis of biogenesis from phenylalanine and condensation with an aldehyde, followed by secondary reactions of methylation and oxidation. An attempt to do this in the laboratory in one case led to an alkaloid, then unknown, but discovered many years later in a Queensland tree. Adding a further carbon atom to the *iso*quinolines formed from two phenylalanine units leads to the berberine group, and hence by rearrangement to the sanguinarine group. Even morphine and related alkaloids, despite superficial appearances, can be derived (hypothetically so far) by chemically probable ring-closures in this series. Such considerations have led to a revision of the original formulæ of both berberine and morphine.

A similar series of alkaloids can be distinguished based on tryptophan instead of phenylalanine. Harmine is a strict analogue; others, such as strychnine, cinchonamine, quinamine and cinchonine, can all be related to a '*para*' berberine type on the basis of a ring-fission postulated by R. B. Woodward. Thus, strychnine and quinine, despite enormous superficial differences, are biogenetically closely related. These ideas have again been fruitful in leading to correct structures for emetine and ajmaline.

Sir Robert said that Nature is very clever; but listening to his survey gave the impression that some chemists at least are not far behind.

Prof. A. J. Birch (Manchester) discussed the use of isotopically labelled compounds—mainly 1-^{14}C-acetic acid, ^{14}C-formic acid and $^{14}CH_3$-methionine—for testing hypotheses based on structural analogies, using moulds as the experimental media. Moulds were chosen because of their ease of growth, the ease of obtaining incorporations, the variety and high yields of some of the compounds produced and their intrinsic interest as antibiotics and antifungal agents. A postulated biosynthesis of griseofulvin by head-to-tail linkage of seven acetic acid units, and appropriate cyclizations, has been confirmed by reference to the degradations of the isotopically labelled substance derived from $CH_3{}^{14}CO_2H$. It was shown that, in some cases at least, C-methylation can occur from methionine or formic acid in the same way as can O-, S- or N-methylation. Among the substances being investigated are terramycin and methymycin. Extensions to terpene biosynthesis were mentioned, and it was shown that $HOCH_2CH_2C(OH)(CH_3)CH_2CO_2H$ (mevalonic acid) is an irreversible intermediate in producing the terpene chains of mycophenolic acid and mycelianamide. Prof. Birch pointed out that the results obtained can be extrapolated to many products from higher plants, notably flavonoids and anthocyanins.

Prof. T. S. Wheeler (University College, Dublin) was not sure whether to serve a vegetarian diet for non-scientists or a meat diet for his colleagues; but he succeeded in producing a tasty well-balanced dish. He gave a summary of the chemical types related to the flavones and flavanones which occur throughout higher plants. He pointed out that the C_6—C_3—C_6 classification of Robinson is of fundamental importance. This turns out to be based probably on a C_6—C_3-unit with a 3 : 4-hydroxylation pattern (derived from shikimic acid) and a C_6-unit (derived from acetic acid) with a 1 : 3 : 5-hydroxylation pattern (giving 5 : 7-hydroxyls in the resulting flavonoid pigment). He turned to consider the supporting evidence for these ideas, obtained by tracer experiments by Geissman and Neish and their collaborators on the biogenesis of quercetin in buckwheat. This work clearly establishes the sequence: shikimic acid → prephenic acid → *p*-coumaric acid + 3 (acetic acid) → a C_6—C_3—C_6 precursor.

Prof. Wheeler emphasized that many of the principles of chemical stability deduced in the laboratory clearly hold also in the biochemical world, and cited the equilibrium between chalcones and flavanones. The presence of a 5-hydroxyl group in the latter stabilizes them by hydrogen-bonding; similarly, a 2′ : 6′-dihydroxy flavanone can become isomerized (via the chalcone) to a more stable 2′ : 5-dihydroxy flavanone. This may account for the lack of occurrence of the latter type in Nature.

Prof. T. R. Seshadri (Delhi) put forward views on the part played by C_8-units in natural products, particularly those found in lichens and in moulds. The typical C_8-unit is that of orsellinic acid (2 : 4-dihydroxy-6-methylbenzoic acid), which enters into many depsides, and by secondary oxidation processes into depsidones. Some C_8-units have an extra carbon atom, which may be CH_3, CH_2OH or CHO, in the 3-position, known to be a chemically active position. The presumption is that it is introduced. Prof. Seshadri considers that the most fundamental unit can be represented as 2 : 4-dihydroxy-6(hydroxymethyl) benzaldehyde, which can undergo various oxidations, reduction and condensation reactions leading to known depsides, depsidones, benzoquinones, anthraquinones and xanthones. He suggested that in some cases hydroxyl groups may have been reduced directly from the phenolic ring, and cited in support the reduction of the monotosylate of orsellinic acid with Raney nickel to obtain a good yield of 6-methyl salicylic acid. Further natural products, including stilbenes, tropolones and compounds related to gladiolic acid, can be produced by variants of the scheme. In the opinion of the present writer, this hypothesis amounts to a partial restatement of the acetic acid theory and its ancillary theory of the introduction of C_1-units, at a less-fundamental level, and is less satisfactory for a general correlation of the compounds. It also appears likely that mould tropolones arise from shikimic acid.

Dr. G. J. Popjak (Medical Research Council Radiopathology Research Unit, London) apologized quite unnecessarily for intruding on a gathering mainly of organic chemists, and explained that some fifteen years ago he had felt compelled to abandon his purely medical approach to atherosclerosis to find out something about the biochemical causes of it, notably the mechanisms of the biosynthesis of cholesterol. In the sequel it seems highly probable that the approach which he helped to pioneer is in fact the only logical one in attempting to cope with the disease. He explained that much of the chemistry was the result of his close collaboration with Dr. J. W. Cornforth. He discussed the earlier isotope work of Bloch and Rittenberg, which showed that acetic acid contributes the twenty-seven carbon atoms of cholesterol (fifteen from CH_3, twelve from CO_2H). An amicable division of the field between the American and British groups has now led to an elucidation of the sources of all the individual carbon atoms in cholesterol (that is, whether from CH_3 or CO_2H). This result, taken in conjunction with a much earlier hypothesis of Robinson that the acyclic triterpene squalene folds, with loss of three carbon atoms, into cholesterol, has permitted the elucidation of the major stages in the biosynthesis. A further great contribution has recently been made by Dr. K. Folkers and his group at Merck and Co., who have shown that the biochemical origin of the isopene unit is mevalonic acid ($HOCH_2CH_2C(OH)(CH_3)CH_2CO_2H$), which loses its carboxyl group in the process of incorporation. The overall process seems to be: acetic acid → X → mevalonic acid → Y → squalene → lanosterol (a 4 : 4 : 14-trimethyl steroid) → a 4 : 4-dimethyl steroid → zymosterol (a C_{27}-steroid with 8 : 14- and 24-double bonds) → desmosterol (5- and 24-double bonds) → cholesterol (5-double bond). The natures of some of the intermediates, notably X and Y, and the exact mechanisms of some of the processes are still not at all clear.

The general impression left by the symposium was of rapid advance and a new air of certainty replacing somewhat misty speculations. However, it is clear that a pencil and paper are still very useful tools to produce useful and fruitful suggestions, if not proofs. Little time was left for discussion, and Sir Robert Robinson regretfully closed the symposium after thanking the speakers.

A. J. BIRCH

CONSTITUTION AND CARE OF THE INFANT ANIMAL

SECTIONS I (Physiology and Biochemistry) and M (Agriculture) of the British Association held a joint session during the recent meeting at Dublin on the subject of the infant animal. Prof. R. A. McCance opened the meeting with a general paper on "The Physiology of the Newborn Animal". He began by pointing out what a tremendous physiological upheaval birth must be, and then alluded briefly to the difficulty of finding one's way through the perplexing maze of species and developmental differences to the great general principles of infant physiology. He proposed, nevertheless, to try to do so, and began by saying a few words about the large volume of fluid outside the cells of all newborn animals. There may be some association, he suggested, between this and the anabolic impulse so characteristic of the fœtus and newborn. Further expansion of the extracellular fluids by experimental means has in his experience materially reduced the catabolism of tissue protein. He then dealt with the ways and means by which the newborn animal is prepared by Nature to withstand the infections to which it is inevitably exposed the moment it leaves the sheltered world *in utero*. He traced out the path by which the macromolecules of γ-globulins and other proteins reach the plasma of the developing organism in the various species, and directed attention to some of the effects of this protein transfer, apart altogether from the establishment of passive immunity. He spent the rest of his time in discussing aspects of homœostasis. He showed, for example, how unstable the body temperature can be in the newborn period, and referred to some of the factors responsible for its maintenance. He took as his examples the poikilothermic newborn rat, the piglet and the human infant, and compared and contrasted them. He then went on to deal with the response to a lack of oxygen, and began by referring to the excellent work which has been done on the subjects of cold and anoxæmia by the great pioneers, such as Harvey, Boyle and particularly Edwards. He made the point that, although there are great species differences, all newborn animals are very tolerant of anoxia. This is due, he believes, to the ability of the newborn animal to utilize anaerobic glycolysis to maintain the structure and function of its essential organs, particularly of its brain. The survival time in nitrogen is largely conditioned by the state of development of this organ, but any study confined to the survival-time tells one nothing about the complex respiratory and cardiovascular changes induced by a lack of oxygen in the first and final days of life. Anaerobic metabolism, he pointed out, utilizes the resources of the body wastefully and leads to the production of potentially dangerous end-products. It also produces less heat. This tends to reduce body temperature, which slows down metabolism all over the body, mitigates to some extent the dangers of the wasteful anaerobic glycolysis, and is an important element in prolonging the lives of anoxic newborn animals, including, in all probability, man. If this is so, resuscitation of the cold blue infant should begin with glucose to provide fuel for glycolysis and oxidation, pass on to re-oxygenation and be followed by warmth only when oxygenation has become effective.

Prof. McCance then passed on to the subject of food, growth and renal function. This last is generally reckoned to be poor by adult standards in the newborn period, yet the concentration of urea in the serum is normal at birth and remains so. Few have seen the extent or significance of this paradox, but investigations carried out at Cambridge have explained it. The power of growth, it would appear, may be far more important than the operation of the kidney in maintaining the concentration of urea in the body fluids within normal limits. 90 per cent of the protein nitrogen in the diet of a rapidly growing animal may be utilized for the synthesis of tissue protein and only 10 per cent of it appear as urea and other end-products to be excreted by the kidney.

The weakness and helplessness of the infant have been a constant theme with philosophers. Helpless it may be in that it cannot stage its own come-back from an abnormal situation—it has to be brought back. But many of the signs of weakness are really marks of strength, if by strength is meant the ability to survive. The secret of handling and caring for the newborn is to make the most use of the strength with which it has been endowed by Nature, and if its stability has been upset, to restore this physiologically and not in some haphazard way which may seem the obvious one at first sight.

The next two speakers dealt with more specialized branches of the subject. Mr. G. A. Lodge, of the Rowett Research Institute, read a factual paper on the nutrition of the young pig. He dealt first with the composition of sow's milk and the quantity secreted at different stages of lactation. The concentration of protein is high in colostrum, associated perhaps with the presence of antibodies; it falls as full milk is established, and thereafter tends to rise, while that of fat and lactose falls. The calcium–phosphorus ratio changes from about 1 : 2 in colostrum to 1 : 0·6 in normal milk.

A piglet left with the sow takes about 1·5 lb. of liquid milk a day during the first week, 2·4 lb. a day during the third to fifth weeks, then consumption drops to 1·7 lb. a day during the eighth week. About 0·8 lb. of dry milk-solids is required to produce each pound of increase in body-weight.

For commercial reasons it is desirable to wean piglets as early as possible, so as to free the sow for the next litter. Weaning at birth has been successful only under laboratory conditions; and since piglets get all their antibodies through the colostrum, elaborate precautions against infection are necessary if they are to be reared without it. From two days of age piglets can be reared on artificial food. They require liquid food at first, and they are unable to digest starch or sucrose or any protein other than casein for the first week or so. From ten days onwards dry meal diets are generally employed. The optimum amount of fat seems to be about 8 per cent, and of protein 25 per cent, decreasing to 18 per cent after the piglet has reached a weight of 25 lb. Piglets ten days old are able to digest starch and all the sugars, though their ability to utilize lactose declines after about three weeks.

The third paper of the meeting, entitled "The Nutrition of the Early Weaned Calf", was given by Dr. J. H. B. Roy, of the National Institute for Research in Dairying. Dr. Roy explained that by weaning he meant removal of the calf from its mother at an early age, rather than changing its diet from liquid to dry food. For centuries the dairy calf has been weaned soon after birth because of the demand for liquid milk for human consumption. The newborn calf, like the adult ruminant, has four stomachs, but only the fourth stomach, or abomasum, is functional, for milk by-passes the rumen and reticulum.

The calf receives all its antibodies through the colostrum. All calves should be given colostrum for the first 24 hr., and preferably for four days after birth if deaths from *E. coli* infections are to be prevented. Certain antibiotics, in particular the tetracyclines, will give protection against these conditions. Calves are normally fed on whole milk for the first three weeks, and thereafter on milk substitutes. Milk substitutes do not give such satisfactory results when fed directly after the colostrum period. The pre-ruminant calf seems to be unable to utilize any carbohydrate other than lactose or glucose, and it cannot tolerate more than 250 gm. of sugar a day. Carbohydrates, therefore, cannot provide the main source of energy in milk substitutes during the early post-natal period; and moreover, a certain amount of fat seems to be essential for the young calf, and, of the milk by-products, probably only buttermilk contains enough of this. If fat is added to reconstituted dried skimmed milk, it must be properly emulsified and homogenized or it will cause diarrhœa. The digestibility of fat by piglets, young guinea pigs and pups has been shown to depend upon the chain-length of the constituent fatty acids rather than on their saturation. The shorter the chain of saturation the greater the digestibility.

This is probably true for the young calf, although the use of fats containing highly unsaturated fatty acids has also been detrimental to the health of young calves.

No suitable substitute for milk protein in the diet of the pre-ruminant calf has yet been found, and even spray-dried skimmed milk which has been processed with a high pre-heating temperature may be of less value than fresh skimmed milk or milk processed at a lower temperature. This effect may be due to the denaturation of the soluble protein by the heat treatment, or to the fact that such milks do not clot with rennet.

The age at which the calf turns over to the ruminant method of digestion depends upon the diet which it has received. The longer it has access to a plentiful supply of milk, the less it will want to eat the fibrous and starchy foods necessary for the functional development of the rumen. It is a great advantage to the farmer to induce his calf to become a ruminant as early as possible, for once the rumen begins to function cheap foods can be used, and there is no longer the same risk of diarrhœa. The ingestion of roughage stretches the walls of the reticulo-rumen and increases their capacity. The rumen papillæ, however, are stimulated by readily absorbable material, not by fibrous foods.

Dr. Roy next turned to the microbial flora of the gut. The abomasum of the young calf supports a large and diverse population of lactobacilli. The typical rumen amylolytic streptococci and protozoa of the adult animal do not become properly established until the rumen pH is stabilized at about neutrality, which does not normally happen until the calf is nearly eight weeks old. The establishment of the rumen microbial flora can be encouraged at an earlier age if the calf can be induced to eat dry food. Grass is by far the cheapest dry food for the young calf, but unfortunately most calves in Britain are born during the winter months when grass is not available in any quantity. With other dry foods most consistently good results have been obtained with weaning at eight weeks, although recently abrupt weaning at three weeks of age has been shown to give satisfactory growth-rates.

In the discussion which followed, Dr. D. P. Cuthbertson asked Dr. Roy whether he believed it better to transfer a calf abruptly or slowly to a ruminant type of diet. Dr. Roy favoured transferring it slowly.

Dr. Magee raised the question of piglet anæmia, which had not been mentioned by Dr. Lodge. A single injection of iron intramuscularly had been found very effective for piglets, and also in certain circumstances for calves. Dr. Roy agreed that if iron is given to calves it raises their hæmoglobin-level, but he pointed out that calves do not generally show clinical signs of anæmia as piglets do, presumably because they grow more slowly.

Mr. D'Arcy asked if anyone knew why feeding freshly harvested barley or rye to pigs has such disastrous effects. His own experience covered two prize sows which had had such severe diarrhœa in consequence that they died within two days. Other speakers said that they had heard about this phenomenon, but no one was able to tell the meeting what the toxic factor, if any, could be.

E. M. WIDDOWSON

PHYSIOLOGICAL EXPEDITION TO THE ANTARCTIC

By Dr. L. G. C. E. PUGH
Medical Research Council Laboratories, Hampstead, London, N.W.3

AN Anglo-American Physiological Expedition will be leaving shortly for the Antarctic to carry out studies connected with human acclimatization to cold. The party will assemble in California at the end of November and travel from there via New Zealand to Ross Island at the edge of the Antarctic Continent. They will be taking part in Operation Deep Freeze II of the International Geophysical Year.

The party is being transported by air under arrangements made by the Office of Naval Research, U.S. Navy, and by the United States Military Air Transport. In this way the team hopes to accomplish a programme in four months, which would otherwise require wintering in the Antarctic and four months travelling.

In spite of common experience that one grows accustomed to cold, as well as anthropological testimony, very little objective evidence in support of cold acclimatization has so far been found. Studies have hitherto been hampered by lack of methods for measuring metabolism and changes in body temperature continuously over periods of days at a time.

Major J. M. Adam, R.A.M.C., and the author, whose participation has been made possible by a generous grant from the Wellcome Trust, will be carrying out studies of this nature on themselves and on members of other expeditions already in the Antarctic. They will use apparatus developed by Mr. H. S. Wolff at the Medical Research Council's Division of Human Physiology at Hampstead, which will enable them to obtain prolonged records of the kind required. Samples of blood plasma will also be collected for lipid analysis.

It is well known that the fatty composition of the blood and tissue lipids of hibernating animals during winter is different from that during summer. The differences are such that the degree of unsaturation of the fatty acids of the lipids is higher, and the melting point lower, in winter than in summer. A preliminary investigation of the blood lipids of persons exposed to intense cold during the British North Greenland Expedition was carried out by Dr. J. E. Lovelock, of the National Institute for Medical Research, Mill Hill. The results suggested that similar changes to those found with hibernating animals may occur in the blood lipids of human beings. Dr. Lovelock will continue his studies on the samples of blood plasma brought back from the Antarctic.

A further reason for interest in the problem of blood lipids is the finding that the fatty-acid composition of the plasma lipids of patients with coronary artery disease has shown differences between them and normal subjects similar to those observed in the winter on the Greenland expedition. This similarity could imply that the regional and social differences in the incidence of coronary artery disease may be as much a consequence of environment as of diet.

The American members of the expedition, led by Dr. Nello Pace, of the University of California, are interested primarily in physiological reactions to stress. The pattern of adrenal cortical response to varying stresses has already been studied by this group on front-line combatants in the Korean War as well as in other stress situations. Surgeon-Commander Miller, of the United States Navy, will be studying the epidemiology of upper respiratory infections among personnel in the Antarctic bases on Ross Island. Antarctic personnel are said to remain almost entirely free of colds, except following the arrival of ships or on opening packing cases and mail. In ordinary communities this mode of infection, namely by contact with contaminated objects, is thought to be unusual, at least as regards the common cold virus.

Some of the expedition's equipment was recently on view at the Medical Research Council's Laboratories at Hampstead. It included sledging rations incorporating a variety of new dehydrated meats and other foods, packaged entirely in plastic bags, thus avoiding the use of tins. The cooking equipment employs propane in place of paraffin, and is claimed to give nearly 80 per cent heating efficiency compared with 40 per cent for the conventional paraffin stoves used previously. Also on view were newly designed sledges and various types of protective clothing and other equipment. It was pointed out that this expedition could afford to be more experimental in its approach to problems of equipment than other expeditions, because it will not be called on to move more than two hundred miles from a well-equipped base.

OBITUARIES

Prof. G. H. Wooldridge

GEORGE HENRY WOOLDRIDGE, emeritus professor of veterinary medicine and the doyen of the Royal Veterinary College, died on August 30 following an operation; he was eighty years of age. For some years a gradual failure of his eyesight had caused him to retire from active participation in the work of the many bodies and societies which he had served so well for many years, and to relinquish his consultation practice in which his services had been in great demand. Mentally and physically he remained in good health, and the illness which caused his death was of a relatively short duration.

He was born at Stoke-on-Trent and was very proud to be a Staffordshire man. He was educated at St. Peter's School at Stoke and at Orme Boys' School, Newcastle-under-Lyme. After serving as junior assistant at E.M. School at Newcastle-under-Lyme (1892–93) he decided to enter the veterinary profession. As was the custom in those days, he was placed as pupil with J. Wilson, of Nantwich, in 1893, before entering the Royal Veterinary College in 1895.

He graduated M.R.C.V.S. in July 1899, gaining first-class honours in the final examination, and he obtained the fellowship of the College in December 1905.

Wooldridge's undergraduate career was one of exceptional merit. He was medallist in biology, chemistry, anatomy, surgery and medicine, and he also won the coveted Coleman Prize and Centenary Medal. After graduation he served for a year as tutor at the Royal Veterinary College. In 1900 he went to the Royal Agricultural College at Cirencester as professor of veterinary science and bacteriology. In 1903 he was appointed professor of veterinary medicine in the Royal Veterinary College of Ireland. He returned to Camden Town in 1908, becoming professor of materia medica and therapeutics in the Royal Veterinary College and with charge of the out-patients department. In 1912 he was translated to the senior post in the Department of Medicine and continued in that chair until his retirement in 1943. He became vice-principal of the College in 1936, and on his retirement he was honoured by being elected emeritus professor of veterinary medicine.

His professional life was in the academic sphere, but he took a great and active interest in all matters appertaining to veterinary science. He served as president of the Central Veterinary Society, the National Veterinary Medical Association (now called the British Veterinary Association), the Royal College of Veterinary Surgeons and the Comparative Medicine Section of the Royal Society of Medicine. He was a vice-president of the Research Defence Society. He served on the council of the Royal Sanitary Institute, where his interest in the hygienic production of food products of animal origin had full scope. He was also honorary veterinary surgeon to the Zoological Society of London for many years. He acted as examiner in medicine, hygiene and meat inspection for several academic and professional bodies. He was joint editor of the *Veterinary Journal* during 1906–14 and he contributed many papers to veterinary literature. In this manner his magnum opus was the two-volume "Encyclopædia of Veterinary Medicine". Many sections of this work came from his own pen.

Wooldridge enjoyed teaching and his contact with students. He entered vigorously into every sphere of college life—sporting, social and academic. He was honoured by his profession on many occasions. The Royal College of Veterinary Surgeons gave him the greatest honour within its power, the Steele Memorial Medal, and the Central Veterinary Society did likewise by the award of its Victory Medal and honorary fellowship. One of the greatest interests of his life and also of Mrs. Wooldridge, his helpmate for fifty years, was their work for the Victoria Veterinary Benevolent Fund. Many who have fallen on bad times have had cause to thank this kindly man and his gentle wife. J. McCUNN

Mr. Leo Bagrow

LEO BAGROW, who died at The Hague on August 9 at the age of seventy-six, was a commanding figure among students of the history of cartography. A scholar with fire in his belly, he possessed outstanding qualities of enthusiasm, determination and thoroughness. These enabled him to pursue his chosen subject continuously for more than half a century and in spite of interruptions caused by the two major political convulsions of our time, in which he was unwillingly involved.

After completing his education in St. Petersburg, Bagrow served, before and during the First World War, in the Russian Imperial Navy, mainly as a hydrographer. Surveys in the Caspian Sea and Gulf of Finland were followed by expeditions to various parts of Siberia and to Kamchatka and by visits to Japan. He was already an ardent collector of early maps, particularly of Asiatic Russia and the Far East, and his first studies were published between 1912 and 1917.

After the Revolution, Bagrow and his wife emigrated in November 1918 to Berlin. Between the wars, missions for commercial firms gave him ample opportunities to continue his search for early maps; he travelled throughout Europe and in Asia, Africa and North America. An extensive knowledge of European libraries is revealed in his invaluable bio-bibliographical studies of sixteenth-century cartographers ("A. Ortelii catalogus cartographorum", 1928–30). In 1935 he founded "Imago Mundi: a Review of Early Cartography"; this annual, of which Nos. 1–3 had appeared by 1939, has provided a vehicle for much of the best work in this field by Bagrow and others. At the same time he initiated a series of facsimiles of early maps entitled "Anecdota Cartographica".

In 1945 a Swedish aircraft carried Bagrow, his wife and their tame sparrow from Berlin to Stockholm, where with stubborn courage he resumed his scientific activity in spite of increasing deafness and the loss of his records and part of his collections. The publication of "Imago Mundi" was recommenced, and ten issues (4–13, 1947–56) were produced with the help of subsidies from Swedish cultural foundations. Other notable post-war works by Bagrow include his essay, "The Origin of Ptolemy's Geographia" (Stockholm, 1945); his "Geschichte der Kartographie" (Berlin, 1951); and three parts of "Anecdota Cartographica" (1948–53). At his death he had completed, and was preparing for publication in English, several important works, including a history of Russian cartography. Bagrow's valuable collection of early maps of Russia was acquired in 1956 by the Houghton Library of Harvard College.

Those who worked long with Leo Bagrow learnt that behind a peremptory temper and formidable obstinacy lay warm human sympathies and a strong and genial humour. R. A. SKELTON

Mr. James Kendall

ALL Jim Kendall's acquaintances, colleagues and friends must have been shocked to hear of his sudden and untimely death on August 24. It is true that he worked hard and played hard, but one would have said he was at the full height of his powers and in a position in the engineering industry for which he was well suited and where he would increasingly extend his influence.

His contribution to the development of nuclear energy in Britain has been considerable, but is not well known. He was responsible for the design and construction of the BEPO pile at Harwell, and for the first production piles at Windscale. These were built at a time when development facilities were limited and naturally are solid, conservative conceptions. How different they are from Kendall's last work with the Atomic Energy Authority, which was concerned with the design and construction of the Dounreay fast breeder reactor. This is certainly one of the most difficult engineering projects undertaken by the Authority, and one which required day-to-day contact with the large development teams that have had to be brought together for this work. At an earlier period, he was made responsible for the engineering laboratory concerned with the development of components for the gaseous diffusion plant at Capenhurst, and perhaps this contributed to an understanding of the outlook of scientists and to the profitable atmosphere of mutual respect between scientists and engineers working on the Dounreay project.

The fact that Kendall's contribution to the development of atomic energy was not better known was in the main due to personal idiosyncrasies. He joined Sir Christopher Hinton and Sir Leonard Owen in the early days at Risley, after serving with them in the Ministry of Supply through the war-time years. This long association may explain to some extent the success he had in branches of engineering where solid academic backing is usually regarded as advantageous. He had no academic qualifications, and no diplomas or membership of professional institutions—indeed, he positively avoided the possibility. He would not have welcomed public honours or awards no matter where they came from, and if he could avoid signing a written document he would do so; but these strange characteristics did not reduce the regard, and often affection, in which he was held by those who knew him.

In his family life similarly he liked to pretend to be an almost Victorian master in his own house; but this only concealed to a degree how fortunate he had been in his choice of a wife. All our sympathies will be extended to her and his daughter.

L. ROTHERHAM

NEWS and VIEWS

Long Ashton Research Station, Bristol: Dr. H. G. H. Kearns, O.B.E.

DR. H. G. H. KEARNS, who succeeds Prof. T. Wallace as director at Long Ashton (see *Nature*, 180, 267; 1957), received his scientific training at Wye College and the School of Agriculture, University of Cambridge. After a period of service in the Zoology Department of the University of Bristol, he was appointed to the staff of the Long Ashton Station in 1931 as an adviser in entomology, but later transferred to the post of research entomologist, which he still occupies. From his appointment until the outbreak of war in 1939 his researches were mainly concerned with the biology of pests of horticultural crops, including fruit and market garden and glasshouse crops, and of basket willows. In his work on fruit crops he made outstanding contributions on the control of serious pests of fruits, notably on capsid bugs, apple and plum sawfly, codling moth and raspberry and strawberry pests, and did valuable work on the formulation of sprays, particularly those containing tar and petroleum oils. His investigations played an important part in the development of comprehensive spray programmes for fruit crops, particularly those suitable for the West Midlands fruit areas.

From 1939 onwards he has specialized on the development of spraying machinery and equipment, and during the War he played an important part in designing and developing machines for county agricultural executive committees to carry out contract spraying in orchards. Largely as the result of his efforts, the committees were able to spray 20,000 acres of orchards annually throughout the war period. After the War he turned his attention to problems of automatic spraying machines and equipment, and he designed and built a number of machines for use both in Britain and in the Colonial Territories. Parallel with these investigations, Dr. Kearns has carried out intensive studies of the physical properties of spray fluids and dusts, which have done much to improve the efficiency and economic usage of these materials. During recent years, in conjunction with the Colonial Office, he has worked on the control of pests and diseases of a number of crops in Jamaica and East Africa, including banana, coconut, coffee and cotton, and one of his machines has also been adopted for ground spraying in locust control campaigns. The outstanding services of Dr. Kearns to entomology and agriculture were recognized by the University of Bristol by his appointment to a readership in entomology in 1950, and by the Government by the award of the O.B.E. in 1954. His appointment as director should ensure the continued development of the work of the Station in accordance with the pattern and high standards set by his predecessors.

Human Physiology and Pharmacology at Adelaide: Prof. R. F. Whelan

DR. R. F. WHELAN, who has been appointed at the age of thirty-four to the chair of human physiology and pharmacology in the University of Adelaide, graduated in medicine in The Queen's University of Belfast in 1946. During 1948–51 he was an assistant lecturer in physiology at The Queen's University, and after working for a year with Prof. Henry Barcroft as a research fellow in the Sherrington School of Physiology, he returned in 1952 to the lectureship he now holds at Belfast. His research interests are mainly in the physiology and pharmacology of the human peripheral circulation. At various times he has collaborated with Prof. A. D. M. Greenfield, Dr. J. T. Shepherd, Dr. I. C. Roddie and others in investigating the effects of cold, adrenaline, nor-adrenaline, intra-arterial injections of gases and the action of the sympathetic nervous system on the blood vessels of the limbs. He has made a special study of the action of histamine, and has developed the use of antihistamines as a tool for investigating the role of histamine in human vascular reactions. At present he is investigating the effects of 5-hydroxytryptamine and its antagonists. He is the author of more than forty papers and holds the degrees of M.D. with high commendation and Ph.D. Dr. Whelan has played an important part in developing the scheme whereby students reading for the honours B.Sc. in physiology at The Queen's University are required to undertake a research project and prepare a paper for publication. He has made short visits to Canada and to several countries in Europe, and will lecture at various universities in Canada and the United States during next December and January.

Academic Freedom in South Africa

THE International Committee on Science and Freedom, in co-operation with the Association of University Teachers, is calling a meeting in the Caxton Hall, Westminster, on November 2, in support of the South African universities in their struggle against compulsory race segregation and government control of higher education for non-whites. The whole of the August issue (No. 9) of the Committee's *Bulletin* (Joint Secretaries, Lime Cottage, 818 Wilmslow Road, Manchester) is devoted to the subject of *apartheid* and its threat to South Africa's universities, and could indeed be described as a working paper for the meeting. The *Bulletin* sets forth in a series of contributions from persons closely concerned with university affairs in South Africa and elsewhere in the British Commonwealth the circumstances and theories which have led to the introduction of the Separate University Education Bill and the consequences that will follow if it becomes law. Father Huddleston points out that the Bill is the logical consequence of the Bantu Education Act, and that with the Native Laws Amendment Bill, simultaneously introduced, which makes it criminal, in certain circumstances, for an African to worship in the same church as his European fellow Christian, and enables the Minister of Native Affairs to prevent any kind of relation, social, political or religious, between the two great South African races in their own land, threatens South Africa's own culture and civilization. Dr. J. W. Cook, of the University of Exeter, who is to be chairman of the November meeting, writes on university traditions in the British Commonwealth, showing how the traditional standards of Western universities have been successfully put into operation in university institutions established in multiracial communities in the British Commonwealth outside South Africa.

Dr. Edgar Brookes, of Natal University, explains the ideology of *apartheid*, and the Hon. A. van der Sandt Centlivres, Chief Justice of South Africa during 1950–57, sums up the issues involved in the Government's proposals for racial segregation in the universities, while Prof. D. Stuart, of Fort Hare University College, shows how the proposed transfer of Fort Hare University College to government control, and also of all higher education for non-whites, would affect the status of staff and students and the standard of teaching. He also describes the philosophy of education which underlies the Government's proposals and will guide it in administering the non-white colleges. The case for *apartheid* is presented by Prof. H. C. Stoker, of Potchefstroom University, who, however, limits himself to the strictly theoretical arguments and does not consider the practical issues, especially the financial difficulties. He draws a distinction between academic freedom and university freedom, which, while making a valid point about the relation between a university and the society in which it exists, seems a little strained when applied to the present context. All in all, the *Bulletin* gives a fair and concise statement of the issues and of the impossibility of reconciling the proposals of the South African Government with the ideals and traditions of the university as accepted and practised elsewhere in the British Commonwealth and throughout the Western world.

European Baccalaureate

A 'EUROPEAN' baccalaureate diploma, recognized by Belgium, France, the Federal Republic of Germany, Italy, Luxembourg and the Netherlands, is to be awarded to students attending the European School in Luxembourg. Governments of the six countries recently signed an agreement officially establishing the School on an international basis for primary and secondary studies. The venture was started in 1953, when an international infant and primary school was opened in Luxembourg for children of members of the European Coal and Steel Authority. Educational advisors from the six countries concerned were later asked by the Authority to extend the School's scope by devising a system of secondary education along the same lines. Methods proposed, which have now been agreed by Ministers of Education in each country, had to provide a comprehensive secondary school programme in four languages—French, German, Italian and Dutch—in which each child could follow studies in his mother tongue. The courses had also to fulfil the requirements of the educational systems of all the six countries so that the children would not be at a disadvantage when they returned home; a synthesis of the various national programmes has been worked out.

The study of modern languages is given an important place in the curriculum, and international exchanges of all kinds are encouraged. Such exchanges are helped by the fact that, from the second year, pupils of different nationalities are given communal lessons in history, geography, biology and, later, in physics, chemistry and art history. According to the recent agreement, students will be examined for the 'European' baccalaureate by an international 'jury' headed by a university professor selected from each of the countries in turn. Successful candidates will be allowed access to universities or other institutions of higher learning in any of the six countries.

Journal of the University of Madras: Centenary Number

THE Universities of Madras, Calcutta and Bombay were founded in 1857, the year of the Indian Mutiny. Now, in more peaceful times, Madras has produced the centenary number of its *Journal* (The Registrar, University, Madras, 5. Rs. 4.00). The issue contains twenty-two articles from scientists in many countries. These include: "The Optical Behaviour of Polycrystalline Solids" by Sir C. V. Raman; "On a New Member of the Cylindrocapsaceae" by M. O. P. Iyengar of the University of Madras; "Metamorphic Geology: Reflexions on Its Past, Present and Future" by H. H. Read; "The International Geophysical Year" by Athelstan Spilhaus, a lecture that was delivered at the University in November 1956; "The Elementary Theory of Population Growth" by J. B. S. Haldane. B. B. Dey's "Fifty Years of Chemistry in Indian Universities" is of considerable general interest, since it illustrates the growing importance of science in India. The *Journal* also contains a résumé of the work of the various scientific departments. The number of these appears to be growing rapidly: the oldest has been in existence for only a quarter of a century and there are now ten. The Department of Geology and Geophysics was founded as recently as 1952.

Conservation of Natural Resources

"The Conservation of Natural Resources" is a series of lectures delivered at the Institution of Civil Engineers during 1956 (London: Institution of Civil Engineers, 1957. 17*s.* 6*d.*; 7*s.* 6*d.* to members). The topic is a vital one for the whole world and particularly so in a small crowded country like Great Britain. Although the primary responsibility for action in this field lies with the Government it is the engineer who has to appraise and solve the problem. There are seven lectures in all. "The Engineer's Contribution to the Conservation of Natural Resources" by Sir Harold Hartley deals mainly with the past. Prof. W. R. Jones in "Mineral Resources" points out that since we have plenty of iron, aluminium and magnesium in the sea the future of a steel/light alloy/concrete economy is assured. Prof. L. Dudley Stamp deals with the "Conservation of Land". He stresses the importance of reclamation and making the most of what land we have in a country with only half an acre per capita. One acre of fertile land is needed on an average to feed one person. Sir Hugh Beaver describes the damage done by air pollution, the annual cost of which was recently estimated at £260,000,000. Sulphur is the main offender, so that gasification of coal would reduce this figure considerably. Dr. W. H. J. Vernon lectured on "The Conservation and Corrosion of Metals" and R. M. Finch, the city engineer of Nottingham, describes the way in which waste materials, such as slag, sewage, refuse and ash, can be used, and the reclamation of derelict land. He gave an encouraging account of the steps taken in Nottingham.

Life in Oceanic Trenches

The first volume of the *Galathea* Reports to be issued (Scientific Results of the Danish Deep-Sea Expedition round the World, 1950–52. Vol. 2. Pp. 253+4 plates. Copenhagen: Danish Scientific Press, 1956. 75 Danish kr.) is devoted to papers on animals obtained by the Expedition in depths mainly greater than 6,000 m. When it is realized that only one trawl haul had been made on the sea-bed at this depth (in 1948, by the Swedish *Albatross* Expedition) before the *Galathea* Expedition set sail, the importance of this volume is immediately apparent. It contains almost the entire record of creatures existing in the hadal depths of the ocean from 6,000 m. to below 10,000 m. The examination of this material has been hastened because of its importance, and the results are presented before any of the other findings of the Expedition. The leaders of this Expedition have established a new nomenclature for the oceanic depths: the term 'abyss' is now limited to the depths between approximately 3,000 m. and 6,000 m., that is to say, the greater part of the oceanic floor; the oceanic trenches below 6,000 m. are referred to as the 'hadal zone'. The distinction seems valid, for the fauna of these trenches is greatly different from that of the level oceanic floor. The hadal fauna described in this volume includes Actinaria, hydroids, an octocoral, holothurians (the dominant group of the hadal fauna), crinoids, polychaetes, isopods, pycnogonids and tanaid crustaceans. More than one hundred specimens belonging to five phyla were taken below 10,000 m. The greater part of the hadal species were new to science, but most of them belonged to genera already known. Where new genera are described there is a tendency, strongly to be deplored, to name them after the ship—*Galatheanthemum*, *Galatheathuria*, *Galathealinum* and *Galatheathauma* are new genera from the hadal or abyssal depths, and not one of them belongs to the family Galatheidae, or even to the same phylum as *Galathea*. But this is a very minor criticism of a volume which will remain the chief or only reference source for the hadal fauna for decades.

Simple Investigations in Biology

The place of the amateur in biological investigation has been brought out by J. E. Marson, rural science organizer to the East Suffolk Education Committee. As a result of investigations in various parts of Britain, Marson showed that nymphs of the water boatman, *Notonecta*, were to be found in ponds in the West Riding of Yorkshire in the summer and early autumn while adults were found at all times of the year; in east Suffolk *Notonecta* nymphs can be found in summer and *Notonecta* adults can only be found in autumn when there are very few nymphs. If Marson's statements are correct, then in the West Riding of Yorkshire the adults live until the year after they are nymphs, while in east Suffolk they die during the same year as they are nymphs. In an article in *School Nature Study* (52, No. 208; July 1957) Marson indicates the value of such observations to schoolchildren and asks for the help of children throughout Britain in preparing a national inquiry into the life-cycle of *Notonecta*.

Zoological Nomenclature

The International Commission on Zoological Nomenclature gives notice that, as from March 30, 1958, it will start voting on the following cases involving the possible use of its plenary powers for the purpose specified against each entry. Full details of these cases were published on September 30 in the *Bulletin of Zoological Nomenclature* (13, Part 9): (1) *Phrynosoma* Wiegmann, 1828, validation (Cl. Reptilia, Order Squamata); (2) *Pentila* Westwood, [1851], validation, and designation for, and for *Liptena* Westwood, [1851], of type species (Cl. Insecta, Order Lepidoptera); (3) *Centris* Fabricius, 1804, designation of type species for; *dimidiata* Fabricius, validation (Cl. Insecta, Order Hymenoptera); (4) *adspersus* Rathke, 1837 (*Palaemon*), protection (Cl. Crustacea, Order Decapoda). A proposal is also made for the adoption of a declaration on the question of the use of the diaeresis sign for zoological names. Comments should be sent as soon as possible in duplicate to Francis Hemming, Secretary to the Commission, 28 Park Village East, Regent's Park, London, N.W.1.

Sunspots during November–December 1956

Two Circulars, Nos. 75 and 76, of the United States Naval Observatory, by Winifred Sawtell Cameron, give the results of the measurements of sunspots secured at the U.S. Naval Observatory or at the Mt. Wilson Observatory; these results are a continuation of those published in the *Monthly Weather Review* from February 1, 1927, until December 31, 1947. The data appear in tabular form, a full explanation being given of the symbols used. In addition, No. 77, "Solar Summary for 1956", provides additional data and includes for each day a summary of the results for each group which was numbered at Mt. Wilson, a table containing only four entries dealing with unnumbered groups, and a table comprising fifty entries of recurrent groups.

Oversea Service Division, Colonial Office

The following appointments have recently been made in the Oversea Service Division, Colonial Office: G. Gamble (agricultural officer, Kenya), provincial agricultural officer, Kenya; J. V. Webdale (agricultural officer, Tanganyika), agricultural officer, Zanzibar; W. J. Harrison (assistant conservator of forests, Western Nigeria), senior assistant conservator of forests, Western Nigeria; H. A. Jones (senior geologist, Department of Geological Survey, Federation of Nigeria), principal geologist, Department of Geological Survey, Federation of Nigeria; W. H. Macleod (senior geologist, Department of Geological Survey, Federation of Nigeria), assistant director, Department of Geological Survey, Federation of Nigeria; S. W. Morel (geologist, Nyasaland), geologist, class 1, Cyprus; R. C. Pargeter (senior geologist, Department of Geological Survey, Federation of Nigeria), assistant director, Department of Geological Survey, Federation of Nigeria; D. C. Hendriks (surveyor, Public Works Department, Jamaica), senior surveyor, Public Works Department, Jamaica; H. C. W. Guy (livestock improvement officer, Kenya), principal livestock improvement officer, Kenya; D. F. Golliger, agricultural officer, British Guiana; I. A. D. Robertson, entomologist, Tanganyika; P. A. Thompson, agricultural officer, Fiji; C. R. Wallace, entomologist, St. Helena; A. S. Cook, temporary industrial chemist, Eastern Nigeria; N. V. Williams, fisheries officer, Northern Rhodesia; M. Crown, assistant conservator of forests, Northern Rhodesia; P. R. Reid, assistant conservator of forests, Federation of Nigeria; R. L. Clark, supernumerary surveyor, British Solomon Islands Protectorate; M. A. R. Cooper, surveyor, Federation of Nigeria; J. G. Olliver, technical officer, Survey Department, Kenya; D. Branagan, veterinary officer, Tanganyika; E. Forest, veterinary officer, Jamaica; A. S. Turnbull, veterinary officer, Jamaica; R. C. Smart, spectrographer, Uganda.

University News: University College of North Staffordshire

The following appointments in the University College of North Staffordshire have been made: Dr. D. J. Bartholomew to a lectureship in social statistics; Dr. E. Corinaldesi to a lectureship in mathematics.

The Polymer Corporation Research Studentship founded at the College in 1954 by the Polymer Corporation of Sarnia, Canada, has been elevated to a post-doctoral Research Fellowship. P. P. Rutherford of Trinity College, Dublin, has been appointed Research Fellow and will collaborate with Dr. P. H. Plesch on cationic polymerization.

The National Coal Board has presented £3,000 to the College for research in the stratigraphy of the North Staffordshire coalfield. Dr. J. R. Haynes has been appointed to work on this project under the direction of Prof. F. W. Cope in the Department of Geology. Unilever Ltd. has given £2,700 to the College for fellowships in the Department of Chemistry.

From October 1958, the College will provide opportunities for students, with no qualification in science at the advanced level of the General Certificate of Education, to take in their first year an additional course which will enable them, if successful, to proceed to the degree of B.A. with honours with at least one science subject as a principal subject. Two principal subjects are required for the degree. Fifteen special places will be reserved annually for candidates for such courses, who must qualify for entrance in the normal way. Further information may be obtained from the Registrar.

Announcements

J. F. D. Greenhalgh, of the Rowett Research Institute, Aberdeen, has been awarded a Drummond Junior Fellowship in nutrition for the year 1957–58.

Awards for study in statistics by persons whose primary field is not statistics but one of the physical, biological or social sciences to which statistics can be applied are offered by the Department of Statistics of the University of Chicago. The awards range from 3,600 to 5,000 dollars on the basis of residence for eleven months. The closing date for application for the academic year 1958–59 is February 15, 1958. Further information can be obtained from the Department of Statistics, Eckhart Hall, University of Chicago, Chicago 37, Illinois.

The seventh International Cancer Congress will take place at the Royal Festival Hall, London, during July 6–12, 1958. Enrolment forms must be received at the Congress Office (45 Lincoln's Inn Fields, London, W.C.2) by January 1, 1958, if a late fee is not to be incurred. Registration forms may be obtained from the Secretary-General at that address.

The ninth International Botanical Congress will be held in Montreal during August 19–29, 1959, at McGill University and the University of Montreal. The programme will include papers and symposia related to all branches of pure and applied botany. A first circular giving information on programmes, accommodation, excursions, and other details will be available early in 1958. Further information can be obtained from Dr. C. Frankton, Secretary-General, Ninth International Botanical Congress, Science Service Building, Ottawa, Ontario.

The Fifteenth International Congress of Zoology, to be held in London in July 1958, will consider for final approval and adoption the new text of the International Code for Zoological Nomenclature as revised by the preceding Congresses held in Paris in 1948 and Copenhagen in 1953. In order to relieve the Congress of some of the work involved in the scrutiny of the draft Code, a Colloquium on Zoological Nomenclature is being organized by the International Trust, to be held in London during the week beginning July 9, 1958, prior to the opening of the Congress. Invitations to the Colloquium have already been issued by the Trust to a large number of zoologists known to be interested in zoological nomenclature, and further invitations to the Colloquium will be issued by the Trust to any other members of the Congress who express a desire to take part in its discussions.

Erratum. Reference was made in *Nature* of August 17, p. 321, to a paper by Mr. L. F. Long (not H. F. Long as printed) on instruments for micrometeorological measurements. In the article it was stated that "... the dew-point is roughly the mean of the dry- and wet-bulb temperatures". This is, as several correspondents have pointed out, incorrect; the wet-bulb temperature is approximately the mean of the dry-bulb and dew-point temperatures, as stated correctly in the original paper.

BILINGUALISM IN EDUCATION

A JOINT meeting of Sections L (Education) and J (Psychology) of the British Association devoted to "Bilingualism in Education" was held in Dublin on September 9. Three papers were read, and they were followed by discussion.

The first was given by Sir Ben Bowen Thomas, Permanent Secretary of the Welsh Department of the Ministry of Education. His subject was "An Administrator's Approach to the Implementation of a Bilingual Education Policy". He defined a bilingual policy in education as one which is designed to enable the average pupil to attain a mastery of his mother tongue and a working competence in the second language current within his society, and if possible to achieve this by the time the pupil reaches his twelfth year, and in any event not later than the end of his period of compulsory education. That the Welsh language should still be standing up to English at all looked like a bit of unrealistic importunity, but this reflected the will to survive of "a strange, intelligent people".

An administrator does not lay down general policy; he must understand it and, within the limits of statutory provision and financial resources, devise ways and means of giving it effect. Education policy in general is justified and sustained by reference to public opinion, both national and local. The policy of bilingualism in education is the result of three social forces, namely: a respect for tradition, the will to survive, and a sense of fair play. An administrator will seek to implement it in a way that supports trends that favour it and gives no offence to forces that may be opposed to it. He has to devise a policy in consultation with local education authorities and have confidence in them to apply it in varying ways. He will not associate bilingualism with political controversy, but deal with it as an educational issue.

In England and Wales, the Ministry places direct responsibility for it on its Welsh Department. Successive Ministers have pronounced in its favour. The administrator implements it according to the provisions of the Education Acts. Three sections of the Education Act of 1944 concern it: the first asks the Minister to promote the education of the people and develop institutions devoted to that purpose. Pre-eminent among these in Wales is the Welsh language. Section 62 requires the Minister to see that enough teachers are forthcoming, including the right kinds. Section 76 provides, with certain safeguards, that children shall be educated according to the wishes of their parents. The administration of these sections means that bilingualism in Welsh education has been increasingly clarified. More competent bilingual teachers have been employed, suitable educational equipment, including more and better books, has been provided, and the range of choice for parents is wider than it used to be, particularly after the increase in the number of Welsh-language schools in urban areas.

Welsh local education authorities have acted singly and collectively. Some have appointed language organizers, have stimulated the production of suitable text-books, and have formulated clear bilingual policies in terms of school organization. Their collective instrument is the Welsh Joint Education Committee, which is working, with the University of Wales, to break the vicious circle of the lack of qualified graduates and teachers due to secondary schools not sending suitably equipped students to the university and the training college, which is due in turn to lack of qualified bilingual teachers in secondary schools. It is subsidizing competent research into bilingualism in education, because there is now great scope for parading prejudices and superficial impressions about bilingualism as authoritative views. This is a process which is exercising a bad influence on public opinion, making unnecessary difficulties for some local authorities at a critical stage of their efforts to apply sound educational policies. Compulsion is out of the question. The conclusion of the Central Advisory Council for Education (Wales) still holds: "We do not anticipate that a measure that would in any way upset the present delicately adjusted equilibrium of educational administration would react at all favourably upon the place of the Welsh language in the schools". If this policy of bilingualism in education is to succeed, statesmen must be able to count on the support of public opinion and administrators, and teachers and parents must have confidence in one another.

The second paper was given by Mr. J. R. Morrison, a Gaelic-speaking Scotsman, who is now on the staff of the Education Department in the University College of Wales, Aberystwyth. He gave some interesting summaries of psychological research work that had been undertaken in Wales, Scotland and Canada, concluding that not enough has been done under satisfactory conditions to justify firm conclusions of any kind.

The results of the Welsh experiments seemed to establish that reactions to emotionally charged words vary according to the language in which the bilingual child hears them: for example, 'nasty', 'wicked', 'sister', when spoken in Welsh to a bilingual child, produced quicker reactions than the English words, whereas 'lazy' had a greater emotional impact in English for the same children, perhaps because English was the dominating language in the school investigated. Girls seem to be more favourably disposed to bilingualism than boys, and children of Welsh-speaking mothers more so than those of Welsh-speaking fathers. Bilingual children usually scored less in tests of intelligence and of English attainment, but in non-verbal intelligence tests they were nearly or quite equal to monoglots, especially if the test used had no time limit. It was only a minority of children that was definitely equally at home in both languages.

Mr. Morrison described in some detail the results of an investigation by a Canadian neurologist. He seemed to have established that the speech areas of the brain begin to lose their sensitivity after a child reaches the age of ten years, and that they are senescent by the age of fourteen. If this is so, the period of primary education is of vital significance for bilingualism. Mr. Morrison concluded that controlled experimentation on a much wider scale than anything that has yet been attempted is necessary before the complexities of the problem can be unravelled and reliable educational guidance given to teachers.

The third paper was given by Prof. E. F. O'Doherty, professor of logic and psychology in University College, Dublin. He dealt with some educational aspects of bilingualism.

In his view, the emotional life of a large number of children is disturbed by the pseudo-bilingualism in which Irish children find themselves in their early years, because they came from English-speaking homes but received their instruction, from their earliest years, through the Irish language. He maintained that the language of the home, whatever it is, is the child's native language, and that it is a mistake to confuse this with the ancestral language of the people to whom he belongs. In nearly all countries there is a bilingual problem, and in nearly all the hundred or more studies available on the topic, investigators have consistently recommended that children should be taught their native, that is, home, language and in other subjects through that medium. Language, a system of symbols, can become a symbol of a different kind—it can become a symbol of nationality or of culture, or of lack of culture; as a symbol of political independence or of nationality it can be valuable, but as a symbol it is dangerous because it may take precedence over the thing that it symbolizes. The primary purpose of language is a social one, and the first society in which it is acquired is the home. The language of the home is always the child's native language, and his mother tongue. To confuse the native language with the conception of an ancestral language may inflict great harm, because it means the by-passing of the child's normal means of social intercourse in favour of what for many, though not all, is the ancestral language. This has many undesirable effects.

It is also important, Prof. O'Doherty said, to distinguish between bilingualism and pseudo-bilingualism. The latter is the position of a person who has achieved a mastery, proportioned to his age and social group, over one means of social intercourse and who has also acquired some knowledge of another means of communication without mastering it. A bilingual person is one who has two vernaculars. This is a rare phenomenon indeed compared with the number of pseudo-bilinguals in any population. Although research is incomplete, there is no denying the impressiveness of the conclusions that monoglot children do better in intelligence tests than their bilingual and pseudo-bilingual brothers. Very often the problem of bilingualism is decided on grounds other than the intelligence or the welfare of the children—politics, tradition, culture, have provided powerful incentives. Where that has happened, bad psychology, bad educational philosophy and bad educational practice have crept in. The emotional life of a large number of children is disturbed by the pseudo-bilingual situation. Unconscious disturbances precipitated by the total or partial breakdown in communication due to the language barrier can produce long-range effects of some magnitude. In Ireland their contribution to the problem of emigration should not be under-estimated.

In the discussion which followed, speakers included teachers from the universities, training colleges and primary schools. On the whole, they expressed fixed attitudes to the subject, and did not bring to the discussion an open-minded willingness to elucidate the subject in its numerous facets. It was therefore inconclusive and rather disappointing. Charge was met by counter-charge, one body of experience was pitted against another, and the points made came entirely from the Irish situation, in which the great majority of the members of the joint session were involved.

RESEARCH ON GELATIN AND GLUE

THE conference on "Recent Advances in Gelatin and Glue Research", organized by the British Gelatine and Glue Research Association, and held in Cambridge during July 1–5, attracted 150 participants. The discussion which ensued after each group of papers was evidence of the success of the conference. Discussions were stimulated in part by the excellent standard of the papers and by the fact that the aim was to discuss but a single protein, albeit one of tremendous physiological and industrial importance. It is hoped to publish the proceedings before the end of this year, edited by G. Stainsby (Pergamon Press, Ltd.).

At the opening ceremony, Mr. S. G. Hudson, chairman of the Research Association, included in his preface to the Conference an especial welcome to the overseas visitors. The Conference was formally opened by Prof. F. J. W. Roughton, one of the visitors to the Association appointed by the Department of Scientific and Industrial Research. He then introduced Prof. L. Pauling, who gave the Conference Lecture, "Polypeptide Chains in Proteins". In proposing a vote of thanks to Prof. Pauling, Mr. I. H. Chayen (British Glues and Chemicals, Ltd.) stressed the interdependence of technology and fundamental science, and emphasized the especial need of the gelatine and glue industry for fundamental research in the protein field.

Prof. Pauling outlined the development of the modern concept of the helical structure of collagen from the earlier classical experiments of Astbury, Bernal and Fankuchen. Although, by admission, Prof. Pauling discussed few new results beyond the idea that hydrogen bonding at the backbone might be at 180° rather than 120°, the lecture set the tone of the meetings. At all the later sessions the helical concept was much in evidence. Sessions were devoted to various subjects, each session being introduced by a speaker who outlined its scope and background, as follows: (1) structure, properties, origin of animal connective tissue (introduced by Prof. K. W. Gustavson, Swedish Tanners Research Association); (2) soluble collagens and molecular weight, shape and structure of gelatins (Dr. J. Pouradier, Kodak-Pathé, Paris); (3) synthetic polypeptides containing proline (Dr. C. H. Bamford, Courtaulds, Maidenhead); (4) conversion of collagen to gelatin and chemical composition (Mr. A. G. Ward, British Gelatine and Glue Research Association); (5) chemical and physical properties of gelatin and glue (Prof. J. D. Ferry, University of Wisconsin); (6) relation of properties to uses (Mr. J. N. Blake, Richard Hodgson and Sons, Ltd., Beverley).

Discussion on the structure of collagen was concerned with the relative merits of the two structures

I and II (Rich and Crick, 1955). The latter structure is preferred, although there is no evidence that structure I is not also present. Structure II, demanding that every third residue be glycine, imposes a sequence reminiscent of the Bergmann hypothesis. Although there is chemical evidence for the repeating sequence gly-pro-hypro, it is cogent to point out the fate of that earlier hypothesis.

Much would seem to depend upon the degree of identity of the constituent chains of the helix (Burge, Cowan and McGavin). Evidence advanced by Boedtker and Doty (1956) suggests that the chains may not be identical.

A paper by G. N. Ramachandran (Madras), in which the modification of collagen and gelatin by chemical means was discussed, raised the question of the transformation of collagen to elastin (Burton *et al.*, 1955), and it was suggested by Partridge in discussion that the term elastin is too often used for signifying a change in physical properties of collagen fibres rather than for describing a definite fibre which has a characteristic amino-acid pattern distinct from that of collagen. That no discussion of the possibility of transforming collagen into elastin by chemical means took place was probably the one failure of the Conference, although it may indicate current opinion. Stoichiometrically, the change from collagen to elastin would involve cataclysmic changes, and from the accepted amino-acid patterns of the two proteins, 100,000 gm. of collagen could only provide amino-acids for 20,000 gm. of elastin. Far more precise and analytical studies are required following the treatment of collagenous tissue with alkaline buffers, and sodium periodate.

Papers on the biosynthesis of collagen (D. S. Jackson, S. Fitton Jackson and R. H. Smith) suggested that this involves the incorporation of proline into peptide linkage in an amount equal to proline plus hydroxyproline ; residues of the latter appearing as a result of oxidation. It is probable that elaboration of banded fibrils is preceded by the formation of a hydroxyproline-rich precursor, and available evidence suggests that synthesis of a soluble precursor in the fibroblasts is followed by extracellular aggregation with the ultimate formation of insoluble fibres. To what extent the aggregation involves the formation of additional co-valent bonds is not known ; neither is it certain that degradation, even under the mildest of conditions, is a reversal of the synthetic pathway. Considerable discussion took place upon the relationship between collagen, soluble collagen (procollagen, etc.) and gelatin, "a relationship still in a state of confusion". Procollagen (acid citrate soluble ; molecular weight 3×10^5) undergoes denaturation upon warming, and two fractions α (molecular weight 80,000, V. N. Orekovich and V. O. Shpikiter, Academy of Medical Sciences, Moscow ; 120,000, P. Doty and T. Nishihara, of Harvard) and β (molecular weight 130,000, Orekovich and Shpikiter ; 230,000, Doty and Nishihara) are formed. The latter workers indicate that the β-fraction is converted into the α-fraction by means of alkali or by long periods at 40° C. They further suggested that the triple helix, demanded by X-ray analyses, may be produced by the folding back of the longer polypeptide chain.

The molecule of procollagen may not contain merely two subunits α and β, since there is, as yet, no evidence to suggest that the α- and β-chains are monodisperse.

That the situation may be more complicated was indicated by a paper by A. Courts and G. Stainsby (British Gelatine and Glue Research Association), which stressed the disparity between molecular weights found by light-scattering techniques (M_w) and by end-group assay (C_n). If one accepts the former as a significant measurement, gelatin of molecular weight 250,000 must have more than one chain (possibly three or four). Since it contains no cystine, alternative cross-linkages must exist. The suggestion of J. Pouradier and his collaborators that aldehydes are present in gelatin and native collagen deserves further study, since it was indicated that such molecules might act as bifunctional reagents. Somewhat at variance with the paper by Courts and Stainsby was that by A. Veis (Armour, Chicago), in which it was suggested that alkali-process gelatin is a linear single-chain polypeptide, whereas acid-process gelatins are "multistranded lateral aggregates of polypeptide chains not in typical Gaussian coil configuration". The work of Courts and Stainsby indicates that gelatin from a limed source is multi-chain, but that acid-process gelatin gave somewhat anomalous results.

Considerable theoretical and practical interest is attached to the changes which occur during the conversion of collagen to gelatin. End-group studies indicate the absence of terminal residues in collagen (whether they are absent, or combined, or fail to react, or are undetectable in the vast molecule is not known). Upon decalcification and alkaline pretreatment of ossein (*p*H 14 at 20° for six days) terminal groups are exposed equivalent in amount to those in the derived gelatin (Courts). By treatment with hydrogen-bond breakers at 20° or by warming to 40–60° the 'parent' gelatin passes into solution. It is supposed that pretreatment leads to fission of peptide bonds, and the presence of up to twelve amino-acids in terminal positions suggests that this fission must be a random process. Whether pretreatment does cause fission of peptide bonds is uncertain. No mention was made of the position of mucopolysaccharides in the build-up of the collagen molecule, and in the degradations induced by decalcification and alkaline-pretreatment of ossein.

The session on amino-acid composition reflected the tremendous debt owed to the ion-exchange method of Moore and Stein (itself based upon the ideas of Martin and Synge and their co-workers). The comparative analyses of J. E. Eastoe and A. A. Leach (British Gelatine and Glue Research Association) and of M. Watson demonstrate overall similarities of collagens and gelatins from different species and indicate variations which may be significant. The full value of this work will only be realized if corresponding physical studies are carried out. In particular, the observations provide a basis for further investigations into the correlations between fibrillar stability and hydroxyproline stability (cf. Gustavson).

The discussion on gel rigidity centred around the work of P. R. Saunders and A. G. Ward (British Gelatine and Glue Research Association), who showed that rigidity is independent of molecular weight from less than 70,000 upwards. Degradation by a variety of proteases and by acid follows the same pathway, although it is unlikely that the same sites in the molecule(s) are attacked by papain, trypsin, chymotrypsin, pepsin and acid. P. Davis and J. W. Janus (Kodak Research Laboratories, Harrow) reported the results of work which supported the view of Grabar (1950), that there is correlation between guanidine side-chains and the protective colloid action and rate of setting of gelatins. The use by Davis of the hypobromite reaction as a means of eliminating guanidine from gelatin cannot be regarded as unequivocal since the reaction mechanism, involving as it does 5 to 6 molecules of hypobromite per guanidine group, is not known. It may well involve side-chains other than guanidine. One pertinent question which received no answer was why soluble collagen does not gel until it has been converted into gelatin although the 'density' of guanidine groups is identical.

The session on synthetic polypeptides focused attention upon the structural information which X-ray and infra-red analyses have provided. It is on such information that present-day views of the structure of collagen are more than a little dependent. With the production of linear polymers of all the individual amino-acids and of some of the vast number of possible co-polymers, it will increasingly be possible to interpret the infra-red spectra of proteins. Indeed, the value of infra-red analysis depends upon the synthesis and analysis of such type substances.

The gelatine and glue industry should also take note of synthetic polymers, since they may ultimately provide means for the 'tailor making' of compounds for individual purposes. In fact, such polymers may be to gelatin what synthetic rubber has been to the natural commodity.

Great credit must go to those who conceived, planned and conducted this Conference. It served many purposes, but most important of all it disseminated information among people of divergent interests. The X-ray crystallographer became aware of properties and problems known to the gelatine industry, and the gelatin manufacturer became more aware of the raw material of his industry and of the structures which produce its peculiar properties, structures which may survive in some form in the derived protein, gelatin. G. R. Tristram

CONTROL OF CHEMICAL ADDITIVES IN FOOD

Advances in science have made available a number of chemicals and newly discovered natural products valuable for their power to aid in the production and utilization of foods. The new, however, is seldom of uncontested virtue. Additives which influence the physical and æsthetic qualities of our foods, and residues of those pesticides which defeat biological enemies, are suspect of affecting adversely the human system. Questions have thus arisen: What risks do we run? How can such risks be kept to a minimum? These have needed both consideration and action, not only in the United Kingdom but also in Canada and the United States, and indeed by the Food and Agriculture Organization and the World Health Organization of the United Nations. It was therefore a happy thought, as the American Bar Association was meeting in London, to hold a joint meeting of the Food Law Institute of the United States, the Food Group of the Society of Chemical Industry, the Society for Analytical Chemistry and the Association of Public Analysts of Great Britain to discuss the control of chemical additives in food. This conference was held on July 26 in London at the Royal Institution.

At the morning session, under the chairmanship of Mr. Charles Wesley Dunn, president of the Food Law Institute of the United States, three papers were given on the official approach to these problems in three different countries, and a fourth on the control of pesticides. At the afternoon session, under the chairmanship of Sir Harry Jephcott, special attention was paid to antibiotics.

American views on additives were stated by Mr. G. P. Larrick and Dr. A. J. Lehman, their paper being read by Mr. John L. Harvey, Deputy Commissioner of Foods and Drugs. Advances in technology have indicated the desirability of amending the present Food, Drugs and Cosmetic Act. In 1950 the Delaney Committee directed attention to the need for more careful control of additives and contaminants. Bills promoting revisions are now before Congress. No new additive should be used until adequately tested by feeding gross quantities for long periods to animals and by finding levels at which no harm occurs. Tests should include consideration given to nutritional effects, clinical and pathological symptoms and effects on reproduction and lactation. Results on one species should be confirmed in another. It is impossible to design a simple or rigid procedure. Moreover, a generous safety factor is desirable in extending to man any application of results obtained on animals. Care in the interpretation of some tests for carcinogens was recommended. It might seem wise to exclude additives which by tests other than oral administration purport to demonstrate potential carcinogenic properties; but in some instances similar results are also given by such common foodstuffs as sugar and lard. The American list of permitted colours has recently been altered by removing three colours, and four others are in process of being removed. None of these colours is carcinogenic so far as is known, but they are not as free from the possibility of being harmful as had previously been believed. Although the addition of chemical substances to food introduced problems, they have served many useful purposes. The conservation of food is necessary, and so is long transportation. Chemical additives enable foods to be available in greater diversity and attractiveness. They also contribute to convenience, thus helping millions of women in the United States to work outside their own homes.

The Canadian view was given in a paper prepared by Dr. C. A. Morrell. To the central question, 'Are the hazards introduced by additives serious?', the answer must be affirmative where large quantities are consumed and negative where only small quantities are consumed. A system of tolerances is thus necessary. Although the Canadian Government regrets interference with private enterprise, consumer confidence is important and definite tolerances must be imposed. The Government must therefore lay down rules and see that they are obeyed. Decisions, however, must clearly be based on sound evidence and be uninfluenced by bureaucracy or caprice. But substances intended to deceive the consumer should never be permitted. The provision of evidence is the duty of industry, but some government research is unavoidable where a conflict of evidence is to be resolved, standards are to be established or methods of analysis are to be devised. Tolerances should be set no higher than is necessary and within what is known to be safe. A general pattern of tests to determine the safety limit can be laid down, but details will often have to be varied. Administrators must be guided by their own experts. The Food and Agriculture Organization and the World Health Organization might help to resolve differences between experts.

The procedure followed in Great Britain to protect consumers against preventable hazards to health or risks of deception was explained by Dr. N. C. Wright, Chief Scientific Adviser (Food) to the Ministry of Agriculture, Fisheries and Food. Food and Drugs Acts establish principles and provide for enforcement. Where precise guidance is desirable, Ministers can make regulations, which are more easily amended than the parent Acts. Ministers look for guidance on technical amendments to their Food Standards Committee, to which medical experts, nominees from industry and officials from departments are appointed. A sub-committee has been studying the need to bring up to date the Preservative Regulations, which happen to approach most nearly to the control of chemical additives. The method used in such cases has been to ask for representations on a group of potential additives from all interested parties, to supplement this with medical and technical evidence from other sources, and to publish a report containing specific recommendations. Any further representations are then considered before Ministers decide on their action. New regulations can be drafted and laid before Parliament for approval. Recently a new system of restriction of the use of colours has been introduced by regulations. There is now a permitted list of colours, but their use is still prohibited in unprocessed meat, fish or vegetables, or in fruit (apart from one exception) to prevent consumer deception. Regulations are being framed to govern the use of antioxidants. A special panel has been set up to examine the medical aspects of the use of antibiotics.

As spokesman also for the World Health Organization and the Food and Agriculture Organization, Dr. Wright pointed out that diversity of conditions among countries makes complete uniformity of regulations impracticable, but the decisions of governments should be based on the widest measure of agreed scientific opinion and should be in harmony if possible. A conference in Geneva in 1955, followed by meetings of two expert committees, had sought to secure the formulation of general principles, suitable biological tests and uniform interpretation of results.

Dr. E. J. Miller extended the picture of British practice by an account of the special precautions devoted to the reduction of hazards to operators, consumers and wild life from agricultural chemicals. An interdepartmental advisory committee advises government departments of risks and formulates recommendations designed to avoid them. After acceptance, these are publicized in order to secure their adoption, although they do not have the force of law. Tolerances for residues are not at present considered adequately enforceable, and preference is therefore given to restrictive conditions by specifying the crops on which individual pesticides may be used, the maximum dosage and the minimum interval before harvesting. A voluntary scheme exists by which manufacturers notify new developments and co-operate in ensuring safe usage.

The status of antibiotics in relation to food in the United States was discussed in a paper by Dr. H. Welch. The use of two antibiotics for the preservation of uncooked poultry, under limiting conditions, has been approved. Such applications are accepted as being useful by the U.S. Department of Agriculture, and a safe tolerance has been fixed by the Food and Drug Administration. All poultry is cooked so that even the permitted amounts of these antibiotics are completely destroyed. Applications to meat and fish, however, are not considered safe. The occurrence of antibiotics in milk has been surveyed. Mastitis is controlled by injection of antibiotics, chiefly penicillin, into the udder. Until three days later, milk may still contain enough antibiotic to prejudice cheese-making. Samples of fluid market milk have often been found positive for penicillin and more rarely for other antibiotics. There is thus a risk that a small proportion of the population may become sensitive to penicillin and suffer allergic reaction. To protect the public, farmers are being educated to prevent bulk supplies of milk from being contaminated; the hazard is stated on every label of the drug and the doses recommended are being substantially reduced.

Canada, according to Dr. C. A. Morrell and Dr. E. S. Thatcher, is prepared to give antibiotics a trial where practical benefit can be safely achieved without risk to their therapeutic value. Canada permits chlortetracycline and oxytetracycline to be used on fish as well as uncooked poultry. All reasonable precautions for safety are satisfied under the conditions specified. The development of resistant microbial strains has not been found of consequence.

The final paper, by Mr. A. L. Bacharach, gave an individual view of some of the complexities of British law as it might apply to antibiotics and of the alleged health hazards attributed to their use in the food industry. The Therapeutic Substances Act prevents the use of thirteen scheduled antibiotics except by registered practitioners, but three of them can be used conditionally in animal feeding-stuffs. The preservatives regulations do not permit the use of antibiotics in human food. There is, however, no control of the use made by farmers of feeds containing them, and veterinary use can lead to contaminated milk. Antibiotics used in horticulture might leave residues, over which there would be no effective legal control. The interpretation of the law is in some doubt as regards nisin and notatin. Experience of pasteurization belies the alleged hazard of encouraging undesirable organisms. Sensitization due to penicillin in milk has not, in fact, been reported, although American records suggest that there are many potential subjects. The suggestion that food spoilage organisms can give warning of the presence of pathogens was vigorously attacked. It was conceded that more information is needed on the magnitude of oral intake of antibiotic which could evoke response in sensitized individuals, whether the allergy is innate or acquired.

It was a tribute to the character of the papers that discussion mainly re-emphasized points made by the speakers, particularly of the complexities of testing and of analysis, and of the difficulties of administrators in fairly summing up issues involving so many diverse factors. A plea was made that the design of toxicity tests should be left to those who had experience of undertaking them. A decision on the adequacy of testing methods should be realistic. Strict specification of the quality of proposed additives would often save time and trouble both in testing and in analysis. It is not enough that manufacturers should be aware of methods of identification and estimation of additives or residues; this information must also be made available to all interested analysts. The American system of relaying such information is noteworthy. Where tolerances are fixed, methods of assay can often be simplified by reference to a standard. In matters of doubt, complete unanimity of opinion in all countries is improbable; but free discussion and free exchange of information could assist in reaching sensible conclusions. Piecemeal decisions should be avoided if possible.

Dr. Bernard Oser suggested that while it is not generally possible to legislate for allergic subjects, some protection might be achieved by appropriate labelling.

It was perhaps surprising that Mr. Bacharach's dismissal of some of the fears felt by those who mistrust the use of antibiotics was not contested.

Mr. Wesley Dunn said that the value of the meeting lay in the opportunity it had provided for discussion of a problem common to many interests, thereby making progress towards its ultimate solution. Sir Harry Jephcott, in summing up, thought uniformity had been brought nearer by this international exchange of ideas, and hoped that this had been only the first of many similar joint meetings.

The papers before the conference will be published in the *Food, Drug and Cosmetic Law Journal*.

MORALE IN INDUSTRY

IN 1953, the Acton Society Trust published, under the title "Size and Morale", the results of an inquiry into the statistically observable relationship between the size of a number of otherwise similar undertakings—in a coalfield, in a large industrial organization, in a commercial group—and certain indices of morale among the workers employed in these undertakings (see *Nature*, February 27, 1954). Size was defined according to the numbers of workers on the books. Morale was measured by various indices of which the most important was the negative one of absenteeism—since, to quote the pamphlet in question, "a man can hardly express his identification with his work more clearly than by whether or not he turns up to perform it".

The results of the inquiry were extremely suggestive. In the coalfield studied, not only was lost time found to increase with size, but it was also established statistically that in similar geological conditions output per man-shift tended to be no higher—and was often in fact appreciably lower—in large pits than in small. Various forms of behaviour suggested that workers in small pits showed greater interest in matters associated with their place of work than those in larger pits. Wages did not appear to have any effect on morale, and it was interesting to find this statistically confirmed. A clear relationship was found to exist between size and sick-leave; between size and the number of accidents; and also between size and the length of time taken to recover from an accident. All this evidence was entirely quantitative and not very useful as a guide to policy. The fact that the size of the unit in which people work is related to their behaviour is not an explanation of the relationship. The earlier studies stopped short at statistical demonstration; they made no attempt to explain what they demonstrated in sociological terms.

The next stage of inquiry called for a different approach, the approach of the social scientist working in individual situations. The inquiry has now been completed and a second-report issued*. It is a qualitative study which tries to find out the reasons for the higher lost time in large establishments and, where practicable, to draw lessons from management policy.

The inquiry was made in a group of twelve manufacturing units which came as near as possible to the ideal requirements for the research. Units of the group varied in size from about twenty to about four thousand people; five of the units were selected for special investigation.

The works selected for study all offered the same wage-rates and conditions of service and the same sick schemes and pension rates; they followed technically the same patterns of work; they were all situated in a large urban area; they had all been under the same administration for many years. They were all alike in employing for the most part labour of an unskilled or semi-skilled character, the small proportion of craftsmen being mainly occupied with maintenance rather than production. There was no significant difference in the age structure of their working forces—a matter which might well make a difference to time lost after accident or illness—nor in the average length of service.

The inquiry confirmed the inverse size-morale effect and showed that poor morale arises from causes which have nothing to do with the worker's satisfaction in, and psychological identification with, his work. Many reasons for good morale in small units were adduced. One is that very small units cannot carry bad time-keepers—they quickly dismiss them; they cause too much dislocation to be tolerated. Evidence showed that the larger works had more than their statistical share of bad time-keepers. This was also true of grumblers, the rumour-mongers, and the chronically discontented trouble-makers. In the small unit such men are easily identified and, if possible, discharged. In the large unit they are likelier to remain submerged and unrecognized and it is in the large units that they are most likely to be found. The trouble-maker has much more scope in a large group. In the small unit, even if he cannot be discharged, he is comparatively innocuous because his colleagues know all about him and can discount what he says. In the large unit the majority do not know him for what he is, and his influence is consequently far more dangerous. His low morale and his high lost time-rate are contagious, and the morale and time-keeping of the works as a whole consequently suffer.

The most important lesson arising from the inquiry is that increasing size is above all an increasing challenge to management—management in the social even more than in the administrative or technical sense. There are disadvantages in size about which management can do little or nothing. A higher incidence of sickness due to greater likelihood of cross-infection is one of these. The wider catchment area for labour is another. So is the tendency of bad time-keepers and 'bad bargains' generally to gravitate to the larger unit. Other disadvantages of size isolated by the inquiry are not similarly intractable. There is no reason why internal discipline should be increasingly handicapped with increasing size by over-extension of the foreman's span of control. A good foreman with a manageable number of men under his control can generate a positive team spirit as well as performing the negative function of checking absenteeism and 'column-dodging'. It is management's job both to select the right foremen (which includes providing the right incentives to their recruitment) and to see that their span of control is suitable.

---

* Size and Morale. Part II. Acton Society Trust. 3s. 6d.

The importance of intermediate management is one of the obvious lessons of this, as of other related inquiries. In order that respect and trust may be generated, it is necessary both that intermediate positions be filled by men of ability and character and that the system within which they work should allow decisions to be made quickly, unequivocally and comprehensibly at the appropriate point. Both the choice and appointment of subordinates and the devising of the structure of authority is the responsibility of top management. It is for top management to devise, and for intermediate management to operate, that system of communications with which the small unit can dispense but which must grow more complex, with increasing size, if instructions are to be understood and morale-destroying misunderstandings are to be avoided. The need of such a system should not be a permanent and inherent handicap of size.

The real difficulty of the big organization, however, springs from the calls that it makes on managerial ability; these outrun the supply of adequately trained managers. The small unit can get on with managers who are competent technicians and reasonably forceful, fair-minded and intelligent characters; the large unit needs specialists, and these, in the numbers required, simply do not exist. The lost-time rates of the large-scale units, and the inadequate morale of which these are largely the symptom and index, reflect this deficiency. To overcome it is an essential step both towards saving the material waste caused by lost time and towards creating a humanly satisfying climate in large-scale industry.

T. H. Hawkins

CONTROL OF PUBLIC EXPENDITURE ON SCIENTIFIC PROJECTS

The third report from the Committee of Public Accounts for the Session 1956–57 has recently been issued*. Reference is made in it to the Treasury Minute of January 31, 1957, rejecting the Committee's recommendation that the Comptroller and Auditor-General should have access to such papers and records of the University Grants Committee as related to non-recurrent grants to the universities; and the Committee expresses appreciation of the fact that, by ensuring that in future the accounting officer is better informed as to the projects on which voted money is being spent and by making much additional information available to the Comptroller and Auditor-General, the Treasury has gone some way towards meeting the Committee's wishes. The Committee recommends that the new arrangements proposed by the Treasury should be given a trial over a period of three years, when the matter might be further reviewed.

Among other matters discussed in this report is the grant by the Department of Scientific and Industrial Research to the University of Manchester towards the construction of the radio-telescope at Jodrell Bank. Originally estimated in March 1952 to cost £335,450, including four years running expenses, the cost had risen in May 1953 to £439,616, towards which the Nuffield Foundation had agreed to contribute £200,000 and the Department £230,000, subject to some conditions relating to financial control, including the requirement that the Department should be consulted if any substantial variation from the expenditure detailed in the approved estimate became necessary. The University entrusted the design work and supervision of construction of the telescope to a firm of consultant engineers under an agreement which provided *inter alia* that prior approval of the University should be obtained for any serious modification of the design or in the cost of the work and for any large variations of contracts, which were to be let only with the written authority of the University. Further rises in costs before the work was completed were expected, and in November 1954 the University notified the Department that the May 1953 estimate might be exceeded by £50,000. In October 1955, however, the University informed the Department orally that the increase was likely to be £240,000 and that it had become clear that the design had been changed substantially without the University's approval. A committee of inquiry was set up jointly by the Department, the Nuffield Foundation and the University, and this committee, which reported on March 15, 1956, recorded what the Department described to the Treasury as a very unsatisfactory position as between the University and the consultants. Nevertheless, the Department considered it imperative that the telescope should be completed and recommended a further grant of one-half the cost above the £430,000 already provided, subject to a limit of £130,000.

The Department informed the Committee of Public Accounts that normally it stated the terms under which the grant would be given to a university, and then trusted the university to expend the grant in a reasonably competent manner: the Department would not intervene in negotiations between a university and its contractors. It was also stated in evidence that the engineering consultant changed the design without the concurrence of the University of Manchester, introducing new structural features which materially increased the complexity and cost; but Prof. A. C. B. Lovell, who was primarily responsible for the outline design and lived on the spot, was apparently not even consulted. The Treasury also agreed that expenditure on the telescope had not been properly controlled and administered by the University, which had not adopted the normal procedure of setting up a building sub-committee to process construction throughout: the Treasury has made the establishment of such a committee a condition of a further grant.

Criticizing the Department for not inquiring more closely into the University's arrangements with the consultant engineers and into the system of control over the design and construction work, the Committee of Public Accounts recommends that in future, when Government departments entrust substantial grants to universities for specific projects, they should seek the advice of the University Grants Committee on such matters as definition of contracts, establishment of university sub-committees responsible for executing the projects and any other measures necessary to control and supervize capital expenditure.

A LATTICE DISTORTION OF ALKALI CHLORIDE CRYSTALS IN THE PRESENCE OF NUCLEOPROTEIN MICROFIBRILS

By J. C. WHITE and P. C. ELMES
Department of Hæmatology (Pathology), Postgraduate Medical School of London, W.12
AND
V. BALASHOV, Prof. R. D. PRESTON, F.R.S., and G. W. RIPLEY
Department of Botany, University of Leeds

It has been shown[1,2] that on slow evaporation of aqueous solutions of alkali chlorides in the presence of some macromolecular substances, the crystals formed are plate-like and contain oriented fibrous inclusions of macromolecules. This phenomenon has been observed with deoxyribonucleic acid, deoxyribonucleoprotein, bronchial mucoprotein, fibrinogen, carboxymethyl cellulose and sodium alginate. The inclusions consist of slender fibres with diameters of 0·1–0·2 micron and varying in length up to several hundred microns. The smallest diameter of microfibrillar inclusions observed is of the order of 90–120 A., and this is most common for deoxyribonucleoprotein[3]. This order of magnitude apparently conforms to the approximate value for the fundamental dimension, typical for a variety of fibriform bodies[4,5].

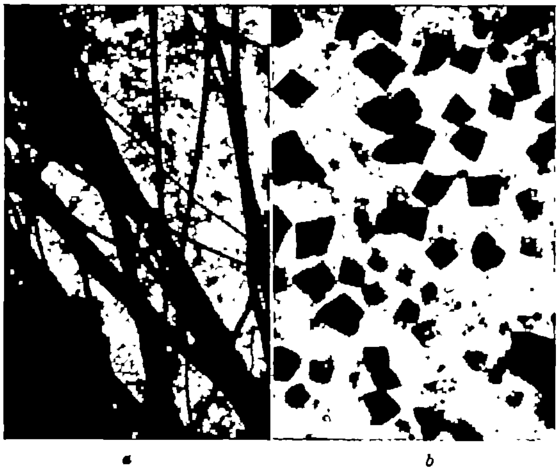

Fig. 1. (a) Electron micrograph of sodium chloride associated with deoxyribonucleoprotein microfibrils. 40 kV. (× c. 4,670). (b) electron micrograph of sodium chloride crystallites, deposited on 'Formvar' film from 80 per cent methanol solution. 40 kV (× 4,670)

Table 1. The Ratios of Some Spacings for Pure Alkali Chlorides and Alkali Chloride Crystals associated with Nucleoprotein Microfibrils

Material	No. of specimens	Ratio d_{111}/d_{200} (Calc. 1·1547)	Ratio d_{111}/d_{220} (Calc. 1·6330)	Ratio d_{220}/d_{200} (Calc. 1·4142)
(a) Pure alkali chlorides (KCl, NaCl, LiCl)	16	1·155 ±0·006	1·633 ±0·012	1·415 ±0·009
(b) Alkali chlorides associated with nucleoprotein microfibrils	19	1·167 ±0·006	1·647 ±0·010	1·414 ±0·006
% deviation		+1·03	+0·857	0·1
Comparison of means of a and b by t test	Degrees of freedom 33	t 5·594 P 0·001 Highly significant	t 3·778 P 0·001 Highly significant	t 0·411 P 0·6–0·7 Not significant

Table 2. Analysis of Variance of the Measurements of Ring Diameters of Pairs of Electron Diffraction Patterns for Alkali Chlorides: KCl, NaCl and LiCl. (a) Pure Alkali Chlorides; (b) Alkali Chlorides associated with Nucleoprotein Microfibrils

Variables	(a) Pure alkali chlorides	(b) Alkali chlorides associated with nucleoprotein microfibrils
Main Effects	*P*	*P*
Between:		
Rings	0·001	0·001
Specimens	0·001	0·001
Pairs of readings	0·02–0·01	Not significant
Observers	Not significant	Not significant
Non-circularity of rings	Not significant	Not significant
First-order Interactions		
Rings-specimens	0·001	0·001
Rings-pairs	Not significant	0·01
Other interactions	Not significant	Not significant
Standard error of observations = error mean square	0·083	0·042

In the course of separation of microfibrillar inclusions from the host crystal by dissolving the alkali chloride in methanol, it was found that for deoxyribonucleoprotein and deoxyribonucleic acid the microfibrils still retain an appreciable amount of salt (Fig. 1a). Even after long-continued washing in methanol and consequent drying *in vacuo* the residual microfibrils, when examined in the electron microscope, continue to give a well-defined electron-diffraction pattern of the alkali chloride, which suggests that the salt crystals are closely associated with the microfibrils of nucleoprotein. The measurement and comparison of these electron-diffraction patterns with the diffraction patterns of the pure alkali chlorides shows that in the case of the salt associated with microfibrils the ratios of the spacings d_{111}/d_{200} and d_{111}/d_{220} are invariably higher than are those for the pure salt.

Table 3. The Change in the Spacing Ratios for Different Alkali Chlorides associated with Nucleoprotein Microfibrils

Salt	Ratio d_{111}/d_{200}		t test P	Ratio d_{111}/d_{220}		t test P
	(a) Pure salt	(b) Salt associated with microfibrils		(a) Pure salt	(b) Salt associated with microfibrils	
Potassium chloride	1·154	1·169	0·01–0·001	1·636	1·653	0·1–·05
Sodium chloride	1·155	1·167	0·05–0·02	1·631	1·651	0·02–0·01
Lithium chloride	1·153	1·158	0·2–0·1	1·632	1·637	0·2–0·1

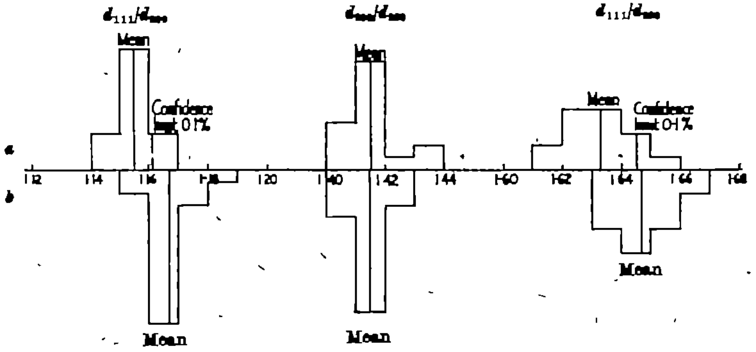

Fig. 2. The distribution of the individual values of the ratios d_{111}/d_{200}, d_{111}/d_{220} and d_{200}/d_{220} for (a) the pure alkali chlorides and (b) alkali chlorides associated with nucleoprotein microfibrils

A series of sixteen samples of pure sodium, potassium and lithium chloride was examined, microcrystalline deposits being prepared on the 'Formvar' substrate by evaporating saturated solutions (1 part of water and 4 parts of methanol) of salts (Fig. 1b).

Similar electron micrographs and diffraction patterns have been taken from the alkali chloride crystals associated with microfibrils of deoxyribonucleic acid and deoxyribonucleoprotein. These include nine samples of sodium chloride, six samples of potassium chloride and four samples of lithium chloride. All diffraction patterns were measured by each of two observers (J. C. W. and P. C. E.) using a glass scale and a × 10 aplanatic lens. The diffraction rings were measured in four diameters, recorded to ± 0·03 mm., and the mean values were used for calculation of the ratios of spacings.

The distribution of the individual values of the ratios d_{111}/d_{200}, d_{111}/d_{220} and d_{200}/d_{220} for the pure alkali chlorides and alkali chlorides associated with microfibrils is shown in Fig. 2. The mean and standard errors for both cases are shown in Table 1 and are also compared by the t test.

Whereas the values of the three ratios for the pure alkali chlorides are in good agreement with the expected ones, the ratios of spacings for the alkali chlorides associated with microfibrils reveal a significant lattice distortion of the salt crystallites. This is shown by the abnormally large ratios d_{111}/d_{200} and d_{111}/d_{220} (Table 1).

The 240 measurements made by two observers on the paired diffraction patterns from samples of pure alkali chlorides were examined by analysis of variance, together with similarly treated samples of alkali chlorides associated with nucleoprotein microfibrils (Table 2). The only sources of large significant error are the specimens and ring diameters, as expected. Ring-specimen interactions are much smaller, and indicate only that differences between specimens affect differences between rings. The only other significant main effect is between pairs of pure alkali chlorides, the direction suggesting that this results from thermal expansion. The effect is not observed for the crystallites associated with microfibrils of nucleoprotein, but in this case it is clear from the electronmicrographs (see Figs. 1a and b) that the crystallites of alkali chloride are appreciably smaller than those of the pure salt. It can be concluded that a number of effects do not add to the error; namely, observer error, lack of circularity of the rings of the diffraction patterns, and higher order interactions. The standard error of the observations is 0·04–0·08 for ring diameters varying from 5·6 to 12·6 mm.

It has already been pointed out[4–9] that some metals prepared in a thin film have an expanded lattice. The general discussion upon the deformation of the cubic F-lattice can be found in Zhdanov and Konusov's paper[10,11]. In the present case of the alkali chlorides associated with nucleoprotein microfibrils, the abnormal spacing ratios may be explained by assuming, for example, that the lattice is no longer a cubic but a tetragonal one.

Indeed, for the spacing ratios d_{111}/d_{200} and d_{111}/d_{220} plotted as functions of axial ratio $a : c$ (Fig. 3) the abnormal experimental values of these two ratios for all three alkali chlorides correspond very closely to the same values of $a : c$. That is, for potassium chloride both ratios correspond to $a : c \simeq 0{\cdot}963$, for sodium chloride to $a : c \simeq 0{\cdot}968$, and for lithium chloride to $a : c \simeq 0{\cdot}991$.

It is of interest to note that the lattice distortion does not affect the three alkali chlorides to the same extent (Table 3 and Fig. 3) and appears to follow the atomic numbers and ionic radii of potassium, sodium and lithium. The magnitude of lattice distortion appears to vary directly with the ionic radii of the alkali metals (ρ = 0·01) and inversely with the polarizing power (ρ 0·01–0·001) and with the lattice energy of the alkali chlorides (ρ 0·05–0·02).

One of us (P. C. E.) held a Medical Research Council clinical research fellowship during part of the course of this work and another (V. B.) a grant from the Nuffield Foundation.

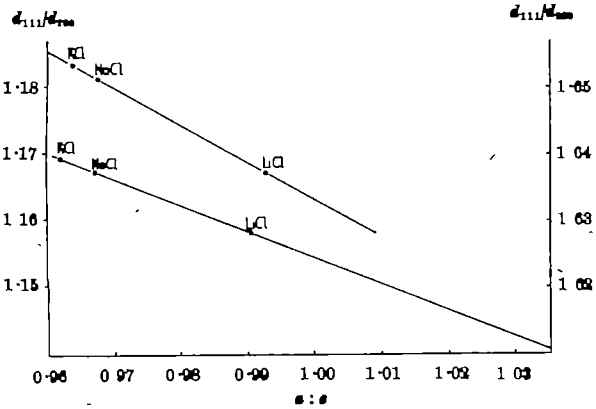

Fig. 3. The relationship between the spacing ratios d_{111}/d_{200} and d_{111}/d_{220} and axial ratio $a : c$

AN INHERENT CHARACTER OF PLANT SPECIES OF DRIER HABITATS

By Dr. M. L. R. PETTERSSON, S. K. F. ELLIS, G. E. J. GRAY and R. S. SMITH
Acton Technical College, London, W.3

THAT angiosperm species of drier habitats (excluding the succulents which have a different metabolic regime) have drier tissues than similar species of moister places, when each is observed in its modal habitat, has become established[1,2]. It is sometimes forgotten that the whole or greater part of this difference might be due to environmentally induced modification, occurring anew in each generation. There is a little direct experimental evidence that at least in some cases the species of drier habitats do in fact have inherently drier tissues, as measured in various ways; though few workers have taken the trouble to compare individuals of such opposed species which have been reared in a common environment, so as to eliminate differences in modification. Thus, Maximov *et al.*[3] found that non-succulent 'xerophytes', such as *Artemisia maritima*, had about twice the vacuolar osmotic pressure of certain 'mesophytes', such as *Erodium ciconium*, which were growing in the same part of the Tiflis Botanical Garden (5+4 species, in nine genera); while Fritsch and Haines[4] appear to find that certain terrestrial algae are inherently drier than certain fresh-water algae (2+2+2 species, in six genera). If this proves to be a general and normal relationship, the inherent character of tissue dryness might be a useful criterion, in breeding for drought resistance, which has not so far been generally used[5].

Consequently some data of 1955–57 should be made known. Six British genera were chosen in which plants were available of two or more species showing known ecological preferences for moister or drier habitats[6]. Comparisons of the fresh-weight/dry-weight ratio, or 'dilation'[6], of comparable laminas were made, within each genus, on plants which had been reared under the same conditions. Three ways were used of eliminating differences due to environmentally induced modification: (*a*) the transplantation of small portions in early spring into standard conditions, so that many new organs could develop during the growing season; (*b*) the comparison of two species growing naturally intermingled in the field, in the same square decimetre or metre; (*c*) the comparison of species raised together from seed in standard artificial conditions.

It is known that dilation, that is, fresh wt./dry wt., varies considerably according to position in organ, nature of organ, position of organ in organism, and according to age, as well as according to environment; so that great care has to be exercised to obtain comparable samples. Due to differences in morphology, size, rhythm, etc., as between genera, one would not expect two plants such as *Quercus robur* L. and *Endymion nonscriptus* (L.) Garcke—of the same community—to have typically the same lamina dilation. But by comparisons within a genus, variance associated with general morphology, etc., can be reduced to a minimum, as in the present comparisons.

Table 1 shows some of our conclusions in condensed form. Each intrageneric comparison shows that the species of the ecologically moister habitat has the greater inherent dilation, the greater inherent fresh-wt./dry-wt. In most separate genera the differences, as so far studied, are already significant. For the group as a whole, the average difference in inherent specific dilation is seen to be more than 40 per cent, and fully significant, with $P < 0·01$. Several other common species of *Ranunculus* and *Veronica* (perennial section) were studied, and showed the same relationship. In *Veronica*, rearing species from seed, method (*c*), gave confirmatory results. It appears that in *Veronica*, at least, the inherent dry weight of the cell is relatively constant, and that dilation is closely correlated with cell size ($r = +0·88$). In the group of six genera studied, there was no association between specific habitat and lamina fresh weight.

When grown under the same conditions, and perhaps for long enough to eliminate previous modifications, Fritsch and Haines[4] found that the dilation in certain green algae increased steeply, from *Pleurococcus naegelii* with $d = 1·7$, to *Zygogonium ericetorum* with $d = 6·2$, to *Spirogyra* sp. with $d = 24$; their respective normal habitats being tree trunks, etc., the soil surface, and fresh water. Here again inherent internal dryness corresponds to dryness of modal habitat. Since the same relationship is reported from algae and angiosperms, the proposition may be put forward, as a hypothesis for further testing: that among green plants it is normal for a genotype of moister modal habitat to have inherently wetter, more dilate, tissues than a similar related genotype of drier modal habitat. It would be interesting also to have information for non-green organisms.

Table 1. Showing the Relationship between Inherent Dryness of Lamina and Dryness of Modal Habitat, in Intrageneric Comparisons. For this Purpose *Glyceria fluitans* R.Br. is regarded as *Poa fluitans* Scop. In each case Plants of the Two Species had been reared in a Common Environment

Genus	Type and number of comparisons	*A*. Species of moister habitat		*B*. Species of drier habitat		Dilation of *A* / Dilation of *B*
		Species	Dilation fresh wt./dry wt.	Species	Dilation fresh wt./dry wt.	
Ranunculus	*abb*	*R. flammula*	7·50	*R. repens*	5·86	1·28
Hypericum	*a*	*H. tetrapterum*	4·67	*H. perforatum*	4·27	1·09
Primula	*a*	*P. vulgaris*	6·20	*P. veris*	3·02	2·05
Veronica	*aaa*	*V. beccabunga*	8·21	*V. chamaedrys*	4·96	1·66
Centaurea	*a*	*C. scabiosa*	9·05	*C. nemoralis*	7·07	1·28
Poa	*a*	*P. fluitans*	6·45	*P. annua*	5·50	1·17
				$P < 0·01$		Mean = 1·42

During the present season, this relationship is being tested for certain economic grasses, cereals and vegetables, of known habitat preference. If the relationship proves general, as is to be expected since for the six genera $P < 0.01$, then a new method is available for selecting progeny during plant breeding. In breeding for drought resistance, tests of drought endurance[5] could be supplemented or replaced by more rapid dilation estimations. There would furthermore be the new possibility of early selection for suitability to medium or moist situations.

A CAROTENE-PROTEIN COMPLEX ISOLATED FROM GREEN LEAVES

By MITSUO NISHIMURA and KEN TAKAMATSU
Botanical Institute, Faculty of Science, University of Tokyo

THE occurrence of carotenoid-protein complexes in certain bacteria[1] and animal tissues[2,3] has been reported, but the literature contains no evidence of their existence in green cells. We have lately succeeded in isolating from chloroplasts of green leaves a coloured proteide containing β-carotene as its component. Although the quantity of the carotene existing in this form was found to be only a minute fraction of the total content of the pigment in chloroplasts, it seemed worth while to examine the properties of this new proteide.

The starting materials used were fresh leaves of parsley or spinach or chloroplasts isolated from them, all of which lead to the isolation of the same substance. In most experiments we used parsley leaves which were treated as follows. 4 kgm. (fresh weight) of the leaves was dipped in 3·4 l. of chilled acetone containing 51 ml. of 28 per cent ammoniacal water, and immediately homogenized in a Waring blendor for 3 min. The acetone used was carefully freed from any trace of contaminating ethanol. This and all the subsequent procedures were carried out at temperatures below 0° C. The homogenate was thoroughly ground in a mortar with quartz sand, and the ground material was centrifuged at 1,700*g* for 8 min. To the supernatant fluid an equal volume of cold acetone was added together with 0·5 gm. of cellulose pulp, and the mixture was kept in an ice-bath for 30 min. The dark green precipitate was collected on a Buchner funnel by suction, and washed with 1 litre of cold acetone–water mixture (3 : 1) containing 5 ml. of 28 per cent ammoniacal water to remove chlorophylls and free carotenoids. The pink-coloured precipitate remaining on the funnel was washed first with 1 litre of two-thirds saturated ammonium sulphate solution (*p*H 8·0), and then with 1 litre of half-saturated solution of the same salt. The precipitate, now orange-red in colour, was extracted with 0·05 *M* disodium hydrogen phosphate solution and centrifuged at 7,000*g* for 15 min. to precipitate the insoluble portion. The extraction procedure was performed three times, and the combined extracts were made to 0·1 saturation with the addition of saturated ammonium sulphate solution (*p*H 8·0). After centrifuging off the precipitate, the supernatant was brought to 0·3 saturation with ammonium sulphate, and the orange-red precipitate formed was collected by centrifugation at 7,000*g* (15 min.). This procedure was repeated three times, and the collected precipitate was dissolved in a minimum volume of water and dialysed against pure water. The dialysate was centrifuged at 24,000*g* for 1 hr., supernate discarded, and the precipitate was washed with a minimum quantity of water by centrifugation. Throughout all these procedures precautions should be taken to avoid acidic reaction of the medium, since the proteide coagulates irreversibly at lower *p*H.

The substance thus obtained was orange-red in colour, and was composed of particles of relatively uniform dimension as may be seen from the electron micrograph shown in Fig. 1. It is apparently soluble in water and shows yellow fluorescence. It contains 9·5 per cent nitrogen (on a dry-weight basis) and gives positive biuret and xanthoproteic reactions as well as the carotenoid reaction of Molisch (appearance of blue colour on adding concentrated sulphuric acid). When treated with a hot ethanol–acetone mixture (1 : 1) and afterwards with ethyl ether, it loses 33 per cent of its dry weight, indicating that the substance is of the nature of a lipoprotein. By treatment with ethanol and afterwards with ether or acetone, it is separated into two parts: a yellow pigment showing Molisch's carotenoid reaction and a colourless protein which is no longer soluble in water. (The separation of the pigment part did not occur when the complex was directly treated with ether or acetone without pretreatment with ethanol. When the material was previously denatured by heat or acid, separation of

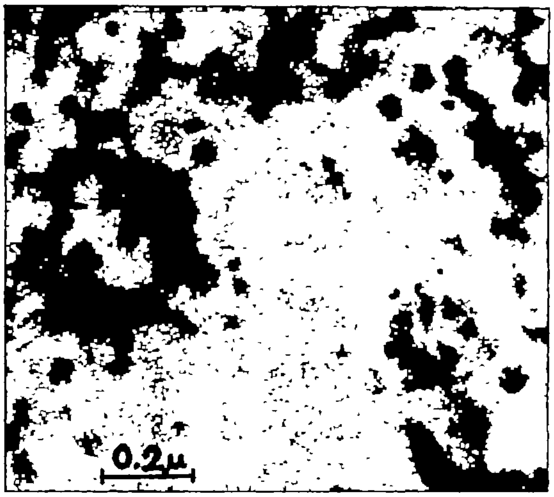

Fig. 1. Electron micrograph of the carotene–protein complex from green leaves (parsley)

the pigment by direct application of ether or acetone could be achieved to some extent; but in this case also the pretreatment with ethanol was necessary for complete separation.) The separated pigment was found, by column and by paper chromatography, to contain a single coloured substance, and when dissolved in *n*-hexane it showed absorption maxima at 452 mμ and 480 mμ with shoulders at 395 mμ and 425 mμ, a spectrum which is precisely identical with that of (all *trans*) β-carotene (Fig. 2). From the absorption measurement of the separated pigment the content of β-carotene in the original complex was calculated to be 2·0 per cent on a dry-weight basis.

The absorption spectrum of the original complex is remarkably different from that of the separated pigment. In Fig. 2 the absorption spectrum of the complex (dissolved in water) is shown with that of the separated pigment (dissolved in *n*-hexane). The complex shows three absorption maxima lying at 280 mμ, 498 mμ and 538 mμ with a shoulder at 460 mμ (Fig. 2). When compared with the spectrum of separated pigment, the two maxima characteristic of the pigment are shifted to longer wave-lengths by about 2×10^3 cm.$^{-1}$ in terms of wave number. The absorption spectrum of the complex is also distinctly different from that of a suspension of β-carotene crystals (*cf.* Shibata[4]). Another remarkable optical property of the complex is that it shows flow birefringence in the dissolved state. Considering the electron-photograph reproduced in Fig. 1, the occurrence of flow birefringence indicates that the particles of the complex are disk-shaped rather than spherical.

From the electron micrograph it was found that the particles are 19 mμ in mean radius with a standard deviation of 6 mμ. If we assume, for the sake of simplicity, a spherical shape for the particles, having a specific volume of 0·75 (in the non-hydrated state), the weight-average particle weight of the complex is estimated to be $5 \cdot 7 \times 10^7$. In Fig. 3 is shown the sedimentation pattern obtained with the aqueous 'solution' of the complex. The sedimentation constant ($s_{20,w}$) was found to be approximately 630 *S*. Based on this figure, and again assuming non-hydrated spherical particles with a partial specific volume of 0·75, the particle weight was found to be $8 \cdot 3 \times 10^7$. This value is in fair agreement with that estimated above on the basis of the electron-micrographic observations. In view of this agreement we may infer that the aqueous 'solution' of the complex is not a true solution, but a suspension of the particles having the sizes found in the electron micrograph.

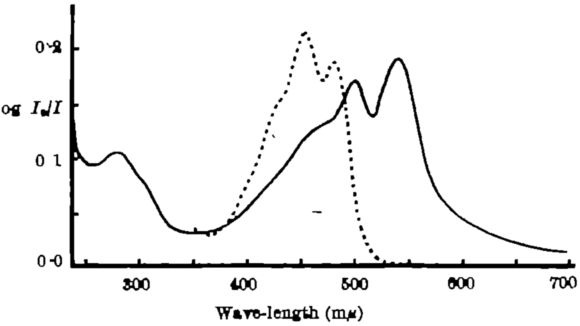

Fig. 2. Comparison of the absorption spectra of the carotene–protein complex dissolved in water (full line) and of the β-carotene separated from it dissolved in *n*-hexane (broken line)

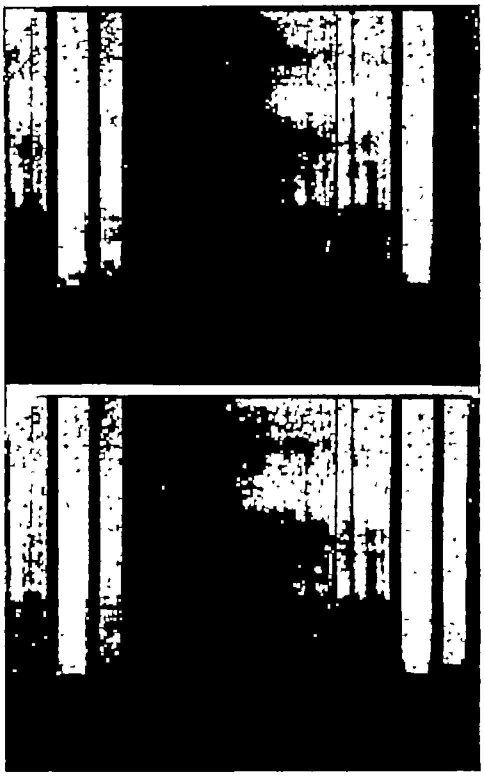

Fig. 3. Sedimentation pattern of the complex; 27,800 *g*, pictures taken at 2-min. intervals

From the estimated value of the particle weight, it is deduced that the mean number of β-carotene molecules attached to each particle is approximately 3×10^3.

It must be emphasized that no reference has been made hitherto to the existence of absorption bands in the absorption spectrum of living green cells corresponding to those of the complex we have isolated. This may be due to the fact that the quantity of the β-carotene existing in the form of the complex is only a minute fraction of the total amount of carotenoids present in green cells. In the case of parsley leaves, the quantity of β-carotene extractable in the form of the complex was only $1 \cdot 73 \times 10^{-3}$ mgm. per gm. dry leaves, whereas the total content of β-carotene was found to be as much as 0·268 mgm. per gm. dry leaves. It seems unlikely that the complex we have obtained was a mere artefact formed during the process of isolation. We believe that the complex represents one of the natural states of β-carotene *in vivo*, playing an active part in the physiology of green leaves.

This work was carried out under the guidance of Prof. H. Tamiya, to whom we are indebted for his interest. We also thank Prof. A. Takamiya and Dr. K. Shibata for advice. Thanks are also due to Mr. T. Samejima for sedimentation measurements, and to the members of the Akashi Manufacturing Company for the electron micrographs. Financial aid from the Ministry of Education is gratefully acknowledged here

Mass-Spectrometric Assay of Elementary Nitrogen

THE method generally used for the estimation of nitrogen-15 in an isotopically enriched organic compound involves the conversion of the organic nitrogen, first to ammonia, and afterwards (by oxidation of the ammonia with alkaline sodium hypobromite) to molecular nitrogen, which is assayed in the mass-spectrometer. Such an assay depends upon the measurement of the intensities of the peaks at mass numbers 28 and 29 due to the ionic species $^{14}N^{14}N^{+}$ and $^{14}N^{15}N^{+}$, respectively. Other substances, which can give rise to ions having similar mass/charge ratios, such as acetone (Me_2CO^{++}) and carbon dioxide or carbon monoxide ($^{12}C^{16}O^{+}$ and $^{13}C^{16}O^{+}$), will also contribute to the observed intensities of these peaks; and corrections for these have to be applied before the intensities of the peaks can be used for calculating the nitrogen-15 content of the nitrogen sample. A correction is also required to allow for the normal nitrogen introduced by the inclusion of air in the gas sample. The accuracy of the determination of nitrogen-15 therefore depends upon the elimination of contaminants so far as possible, and upon the application of adequate corrections for those contaminants which cannot be removed.

The procedure for the preparation of nitrogen samples has been described in detail by Rittenberg[1], who assumes the principal contaminants to be carbon dioxide, from carbonate present in the alkaline hypobromite, and air. The presence of air in the sample is indicated by peaks at mass numbers 32 ($^{16}O^{16}O^{+}$) and 40 (A^{+}), and the former, because of its greater intensity, has been used for calculating the correction to be applied for the contribution of normal atmospheric nitrogen. The existence of a peak at mass number 40 seems to have been taken as confirmation that *all* the oxygen in the sample was of atmospheric origin. However, using Rittenberg's procedure for the preparation of nitrogen samples, we found that in most cases the argon peak, at mass 40, was much too small to justify this assumption. The ratio of the intensities of the peaks at mass numbers 32 and 40, for a sample of air in the mass-spectrometer, was 13 : 1. Table 1 presents results showing that the relative intensities of these peaks in the nitrogen samples analysed was much greater than this.

The value of the ratio of the intensities of the 32 and 40 peaks seems to be influenced by the history of the alkaline hypobromite used in the oxidation of the ammonia to elementary nitrogen. When this material was new, that is, less than one week old, and had been stored at 0° C., the ratio of the peaks at mass numbers 32 and 40 was 100–200; whereas, when the hypobromite, though new, had been allowed to stand at room temperature for 12 hr., before storage at 0°, the ratio of the peaks was only 20–60. Small bubbles of gas were generated in the body of the liquid while the hypobromite stood at room temperature. It seems from these results that some free oxygen is formed during the reaction of ammonia with the alkaline hypobromite, and hence it will be more accurate to correct the peaks at mass numbers 28 and 29 for the presence of normal atmospheric nitrogen using the peak at mass 40, due to argon.

The correction for the contribution of $^{12}C^{16}O^{+}$ and $^{13}C^{16}O^{+}$ from carbon dioxide has been calculated (Rittenberg[1]) from the intensity of the peak at mass number 44, assuming this to be due to $^{12}C^{16}O^{16}O^{+}$. It would therefore be expected that the ratio of the intensities of the peaks at mass numbers 44 and 45 would be constant, indicative of the relative abundance of the two carbon isotopes ^{12}C and ^{13}C. It has been observed, however, that the ratio of the intensities of the peaks at mass numbers 44 and 45 is approximately equal to that of the peaks at mass numbers 28 and 29. This is more readily explained if nitrous oxide (as $^{14}N^{14}N^{16}O^{+}$ and $^{14}N^{15}N^{16}O^{+}$) and not carbon dioxide is responsible for the peaks at mass numbers 44 and 45. Clusius and Rechnitz[2] have already reported the production of nitrous oxide by the interaction of alkaline hypobromite and ammonium salts, and the results presented here confirm this. Again, the newer samples of hypobromite were found to be the more vigorous oxidants, producing larger peaks at mass numbers 44 and 45. In all the gas samples, nitrous oxide seemed to account for much the largest part of the mass 44 peak. Hence there seems to be no reason to correct for the carbon

Table 1

Source of nitrogen sample	Observed intensities of peaks						Ratio of peak intensities	
	Mass 28	Mass 29	Mass 32	Mass 40	Mass 44	Mass 45	Mass 28 / Mass 29	Mass 44 / Mass 45

Amino-acids containing 15 per cent of ^{15}N	85·36 61·21 39·12 39·84 79·65	29·62 21·25 13·65 13·98 27·65	0·727 0·530 0·341 0·596 0·283	0·004 0·002 0·001 0·001 0·021	1·130 0·798 0·502 0·998 0·520	0·376 0·270 0·170 0·347 0·180	2·88 2·88 2·87 2·86 2·87	3·01 2·95 2·92 2·88 2·89
Ammonium chloride containing 15 per cent of ^{15}N	72·22	63·79	0·082	—	0·169	0·111	1·13	1·52

dioxide in the gas sample, since so little is present when the normal precautions are taken to exclude carbonate from the alkaline hypobromite solution; and the correction factor is small anyway. The presence of nitrous oxide in the gas sample is of interest in accounting for the appearance of a peak at mass number 30, which is much larger than would be expected from the $^{15}N^{15}N^+$ contribution. In the mass-spectrometer, the rupture of nitrous oxide gives NO^+, rather than N_2^+, and this completely masks the contribution of the $^{15}N^{15}N^+$ to the peak at mass number 30, even when the ^{15}N content of the nitrogen sample is quite large (15–18 atoms per cent).

The nitrous oxide may be eliminated, if it is so desired, by placing a liquid-air trap between the generator and the gas sample tube. However, there does not seem to be any way of avoiding the production of free oxygen during the preparation of the nitrogen sample. The small intensity of the peak at mass number 40 makes its accurate measurement difficult, and where the intensities of the peaks at mass numbers 32 and 40 correspond, then a correction for air, based on the size of the mass 32 peak, will be more accurate. However, in nearly all the results which we obtained, the use of the mass 40 peak gave a considerably smaller correction than that of the 32 peak, and was presumably more accurate.

Aerodynamic Drag of Perforated Plates

We have recently conducted wind-tunnel experiments to determine the aerodynamic drag of perforated plates at zero incidence by the wake transverse method. The plates have no protuberances, yet they are aerodynamically rough and give a drag comparable with that of plates covered with protruding roughness of the same size and spacing as the holes.

The non-dimensional quantities which could affect the drag are: (1) the Reynolds number of the chord of the plate; (2) the Reynolds number of the diameter of the holes; (3) the ratio of the area of the holes to the area of the plate; (4) the ratio of hole diameter to plate thickness. During the experiments, the airspeed, plate chord, plate thickness and total area of the holes remained constant, while the hole diameter was varied. Thus ratios (1) and (3) were constant, their values being $3 \cdot 5 \times 10^5$ and 0·355 respectively.

The plates were of a double thickness of 18-gauge perforated plate with the holes coinciding but with a sheet of tissue paper sandwiched between them. The leading edge of each was cut on a line through solid metal and was not sharpened. Therefore, the measured drag included surface drag and form drag due to the frontal area. To assess the latter, the drag coefficient of a smooth plate of the same size and thickness was measured and found to be 0·023, which is more than double the value 0·011 expected for a very thin smooth plate in turbulent flow[1]. The difference, 0·012, may be ascribed to the form drag, and may be subtracted from the drag coefficients of the other plates to obtain that part of the drag due to the surface itself.

Table 1 Drag of Perforated Plates

Reynolds number of tests, $3 \cdot 5 \times 10^5$. Chord of plate, 6¼ in.

Hole diameter (in.)	Hole diameter/plate thickness	Hole Reynolds No.	Drag coefficient: With paper sandwiched: As measured	Drag coefficient: With paper sandwiched: Corrected for frontal area	Drag coefficient: Without paper: As measured	Drag coefficient: Without paper: Corrected for frontal area
No holes	—	—	0·023	0·011	0·023	0·011
0·125	2·27	7×10^3	0·033	0·021	0·071	0·059
1·125	21·6	$6 \cdot 3 \times 10^4$	0·033	0·021	0·038	0·026
4·5	84	$2 \cdot 5 \times 10^5$	0·025	0·013	0·028	0·016

The sandwiching of paper between the plates produces the effect of a flat plate covered with a number of cylindrical pits the depths of which equal the plate thickness. The results are summarized in Table 1, from which it is seen the drag considerably exceeds that of a smooth plate and provides evidence of vigorous interchange between the fluid in the hollows and the passing stream.

Further tests were made at the same Reynolds number, after removing the paper from between the plates, thus allowing turbulent transverse velocity components to transfer momentum deeper into the plates where it could build pressures on more of the forward facing surface of each perforation. From Table 1, it is seen that the drag is now greater than that when the paper is preventing through-flow.

Thus perforations or hollows can give rise to great aerodynamic drag, so that a surface entirely devoid of protrusions may behave as if extremely rough. This property may be useful in the design of energy dissipators.

High-Efficiency Columns for the Analysis of Hydrocarbons by Gas-Liquid Chromatography

Following the work of Keulemans and Kwantes[1], the factors affecting column efficiency have been examined further, and the conditions required to obtain optimum column-efficiency have been determined. Important factors affecting column efficiency are the correct grade of column support, the quantity of liquid phase on the support and the dimensions of the column. Column efficiencies[2] of 12,000 theoretical plates may be obtained using the following conditions:

Column length	25 ft.
Column diameter	4 mm.
Column temperature	78° C.
Carrier gas	25 per cent nitrogen, 75 per cent hydrogen
Carrier gas flow	37 ml./min.
Column support	Johns-Manville C22 insulating brick
Support grade	60–100 *B.S.* mesh
Liquid phase on support	5 per cent w/w
Column charge	< 400 μgm.

A chromatogram of a synthetic mixture of *n*-pentane, *n*-hexane, *n*-heptane, *n*-octane, methyl*cyclo*pentane, methyl*cyclo*hexane, benzene, toluene, ethylbenzene, *o*-xylene, *m*-xylene and *p*-xylene is shown in Fig. 1. Under these conditions, separation of *m*- and *p*-xylene is shown. Prior to this work, high efficiencies could not be obtained by merely increasing column length. The above conditions are such that column efficiency is approximately a linear function of the column length. Doubling the length of the column results in almost twice the column efficiency.

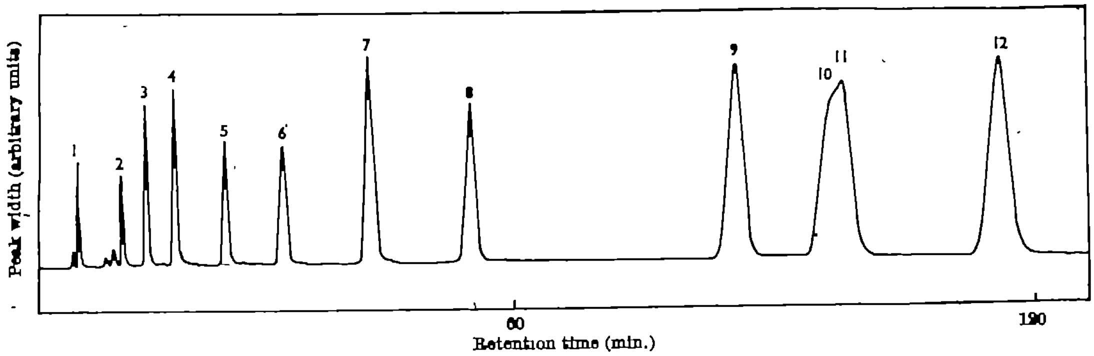

Fig. 1. Chromatogram of a synthetic mixture: (1) *n*-pentane; (2) *n*-hexane; (3) methyl*cyclo*pentane; (4) benzene; (5) *n*-heptane; (6) methyl*cyclo*hexane; (7) toluene; (8) *n*-octane; (9) ethyl benzene; (10) *p*-xylene; (11) *m*-xylene; (12) *o*-xylene

An important factor influencing the efficiency produced by the 12,000 plate column is the total quantity of charge placed on the column. If the charge is greater than 400 μgm., or if more than 80 μgm. of any individual component is present, tailing of the emergent peaks occurs with a resulting fall in column efficiency. An improved form of the hydrogen flame detector[3] was used in this work. Details will be published elsewhere.

Electric Strength of Unsaturated Hydrocarbon Gases

Previous work[1] has indicated that a larger number of gaseous hydrocarbons should be studied before a comprehensive theory of the influence of molecular structure on electric breakdown can be advanced.

The paraffin series has been extended by *Vs-pd* measurements[2] in *n*-pentane and *n*-hexane and their cyclo-derivatives together with *n*-octane, whereas hexene-1 and isoprene are added to the mon- and di-olefin series respectively.

Using the simple Devins and Crowe[3] picture, the following relative composite cross-sections are determined:

θ_{C-H}	θ_{C-C}	$\theta_{C=C}$	$\theta_{C\equiv C}$
1·0	0·85 1·0 (cyclo-compounds)	8·5 (mon-olefins) 9·4 (di-olefins)	10·5

Contrary to other published results[4], the carbon–carbon single bond is found not to be zero, but of the same order of magnitude as the carbon–hydrogen single bond. This discrepancy can be attributed to the elimination of space charge effects and the extended measurements both as regards the number and variety of hydrocarbons investigated and the *pd* range over which each member was tested; where necessary, *Vs-pd* measurements were carried out at an elevated temperature. This makes the present interpretation more reliable. For example, Crowe and Devins[4] make no reference to their earlier reported breakdown measurements[5], which differ by as much as 20 per cent and are in general agreement with previous work[1].

Except for small pulse activity due to the electronic excitation-levels being non-dissociative[6], no anomalous[4] result was obtained for the cyclo-paraffins, and as to be expected, the *Vs-pd* characteristic of *cyclo*-hexane exceeded that of *cyclo*-pentane by a comfortable margin over the entire *pd* range.

The effect of alkyl substitution around the carbon–carbon double bond has been further investigated by *Vs-pd* measurements in *iso*-butene, *cis*- and *trans*-butene, trimethylethylene and *cyclo*-pentene.

Correlation between breakdown measurements and ultra-violet spectra for these compounds, one of the aims of this work, is good. For example, *cis*-butene 2 and *cyclo*-pentene yielded the same *Vs-pd* characteristic whereas a differing characteristic was obtained for *cis*- and *trans*-butene 2, in agreement with ultra-violet work.

More complete reports, one of them in collaboration with T. J. Lewis, will be published elsewhere.

A maintenance grant from the Department of Scientific and Industrial Research and lately the

award of an I.C.I. Fellowship by the University of London are gratefully acknowledged.

Occurrence of Gamma-Guanidinobutyric Acid

In the course of studies on soluble nitrogenous extractives from various sources using paper chromatography, γ-guanidinobutyric acid was found to be rather widely distributed in Nature. Using paper chromatography, we have identified this guanidine compound in some insects, in various edible fruits and in the tissues and body fluids of higher mammals, and we have isolated it from cattle brains.

The chromatographic survey was performed as follows. The tissues from various sources were homogenized in the cold with 70–75 per cent ethanol (in juicy fruits such as the melons, 95 per cent ethanol was used). The homogenates were left in the ice-box at 4° C. overnight. After centrifugation, the supernatant fluid was passed through a column of 'Dowex-50' resin in the hydrogen cycle. The column was washed thoroughly with distilled water. The amino-acids, including the γ-guanidinobutyric acid, were eluted with about 14 per cent ammonia. The eluate was lyophilized after removal of ammonia under vacuum at 25°. The solids were dissolved in a minimum amount of water and used for identification purposes. Preliminary testing for the presence of γ-guanidinobutyric acid was carried out using one-dimensional paper chromatography and *t*-butyl alcohol/formic acid/water (70 : 15 : 15) as solvent. When a positive Sakaguchi test was obtained, two-dimensional chromatograms[1,2] of the unknown were run with and without added authentic γ-guanidinobutyric acid. Additional evidence for the identity of the compound was obtained with material eluted by water from strips of one-dimensional chromatograms. The eluted material was degraded with barium hydroxide to yield γ-aminobutyric acid according to the method of Rivard and Carter[3] for the conversion of arginine to ornithine. The chromatographic characteristics of the natural compounds as well as their R_F and R(β-alanine) values were then determined.

Isolation of γ-guanidinobutyric acid. A preliminary experiment for the isolation of this compound was attempted on a small scale. A 70 per cent ethanol extract of 1·5 kgm. of cattle brains was prepared. The amino-acids as well as guanidine compounds of the extract were adsorbed on a 'Dowex-50' resin in the hydrogen cycle and eluted with ammonia. The eluate, after removal of ammonia under vacuum, was lyophilized. The dried material was used for paper chromatography or for the fractionation of γ-guanidinobutyric acid as follows. A solution of the dried material was first fractionated in a column of 'Dowex-1' resin in the hydroxyl cycle. Distilled water was used as eluting agent and the fraction containing the γ-guanidinobutyric acid was collected and chromatographed in a column of 'Dowex-50' resin in the acid cycle, with 1 N and 2 N hydrochloric acid as eluting agents. After several recrystallizations from 50 per cent ethanol, the final product was insufficient for elemental analysis. However, it is chromatographically pure, and further, on treatment with barium hydroxide, it yields a compound indistinguishable chromatographically from a known sample of γ-aminobutyric acid. The latter does not form a copper complex, since it moves through a barrier of copper carbonate[4] on a paper chromatogram. Both the natural acids give the same R_F and R(β-alanine) values as the known synthetic acids, and both have the same mobilities in paper electrophoresis at pH 8·6 as the respective synthetic acids (Table 2).

Table 1. Occurrence of γ-Guanidinobutyric Acid in Various Sources

Source tested	Amount (μgm./gm. wet weight)
Fruits:	
Banana (*Musa sapientum*)	5–10
Bitter melon (*Momordica charantia* L.)	0
Cantaloupe (*Cucumis melo*)	1–5
Date (*Phoenix dactylifera*)	10–20
Honeydew melon (*Cucumis melo*)	0
Mango (*Mangifera indica*)	2–10
Papaya (*Carica papaya*)	1–5
Persian melon (*Cucumis melo*)	1–5
Strawberry (*Fragaria chiloensis*)	1–5
Watermelon (*Cucumis melo*)	2–10
Insects:	
Aedes aegypti—Tissue	10–20
Excreta	(10–20 μgm./mgm. N)
Culex pipiens—Excreta	(5–15 μgm./mgm. N)
Anopheles quadrimaculatus—Excreta	(5–20 μgm./mgm. N)
Silkworm pupae (*Bombyx mori*)—Tissue	10–20
Vertebrates:	
Dog—Brain	≃ 8
Kidney	5–10
Liver	1–5
Urines	+
Cattle—Brains	≃ 5
Human—Brains	5–10
Some urines	(1–20 mgm./day)

Table 1 gives the distribution and occurrence of the guanidine compound in various sources. The values are only approximations. They were obtained by visual comparison of chromatograms of the unknown and known γ-guanidinobutyric acid. In certain cases, paper electrophoresis of the unknown and known were also used.

Gamma-guanidinobutyric acid was first isolated by Kutscher[5] among the oxidation products of arginine. Later, studies in marine invertebrates indicated that γ-guanidinobutyric acid arises from arginine by the action of an L-amino-acid oxidase and subsequent oxidative decarboxylation[6]. It has recently been found by J. Pisano and associates (personal communication) that γ-guanidinobutyric acid could be formed by a transamidination reaction in the kidney between arginine as a donor and γ-aminobutyric acid as the acceptor of the amidine moiety. Recent studies by Walker[7] have shown that mammalian kidney carries out transamidination reactions such

Table 2. R_F and R (β-alanine) Values of Natural and Synthetic γ-Guanidinobutyric Acid, Natural and Synthetic γ-Aminobutyric Acid

	R_F		R(β-alanine)	
	Solvent *A*	Solvent *B*	Solvent *A*	Solvent *B*
γ-Guanidinobutyric acid (natural)	0·65	0·11	1·54	1·67
γ-Guanidinobutyric acid (synthetic)	0·65	0·11	1·49	1·64
γ-Aminobutyric acid (natural)	0·52	0·05	1·18	1·16
γ-Aminobutyric acid (synthetic)	0·52	0·05	1·17	1·12

Solvent *A*: *t*-Butyl alcohol/formic acid/water (70 : 15 : 15).
Solvent *B*: *t*-Amyl alcohol/2,4-lutidine/water (178 : 178 : 110).

that any donor (for example, canavanine, arginine or guanidinoacetate) could transfer its amidine group to any acceptor (for example, ornithine, canaline, glycine or hydroxylamine). It was shown by Kobayashi[8] that γ-guanidinobutyric acid was degraded to γ-aminobutyric acid by a 'heteroarginase' from an extract of rabbit intestine mucous membrane. The latter compound could also arise from glutamic acid by the action of a decarboxylase[9].

Recent findings of Bazemore *et al.*[10] indicated that γ-aminobutyric acid has a neurophysiological activity. The existence of the γ-guanidino analogue in vertebrates as reported here, and the interconvertibility of these two butyric acids into each other in enzymatic reactions, suggest that both compounds may well be playing a part in some nervous processes.

The substance of this communication was presented at the 131st National Meeting of the American Chemical Society, Miami, Florida, 1957, and a detailed account is being prepared.

Conical Paper Chromatography

A CIRCULAR filter paper suitable for partition paper chromatography is cut so that it can be made into a cone. A number of origins are marked at adequate intervals near the lower edge, the standard and unknown solutions are dropped on these origins (see Fig. 1) and chromatographic development allowed to take place in an upward direction. The cone is immersed in the solvent in a Petri dish placed in a glass vessel with a tight lid (see Fig. 2).

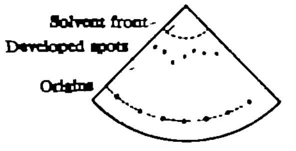

Fig. 1

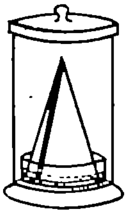

Fig. 2

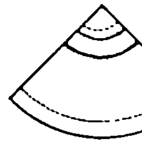

Fig. 3

If a continuous line of test solution is applied and then the development is performed, the resulting chromatogram will appear as a series of arcs (see Fig. 3). This latter procedure is especially useful in preparatory chromatography, since the arc required can be readily chosen and cut off.

Particular advantages of this method are that special apparatus is not required; a comparatively smaller size of filter paper and less solvent are required than some of the methods generally used. The development of many materials simultaneously is possible on one chromatogram; the zones are concentrated, so that dilute solutions which would not be sufficiently strong for conventional methods of paper chromatography can be chromatographed by this method. The method can be particularly useful in preparative chromatography.

Using this method of conical paper chromatography, I have been able to identify the green pigment of the Indian lotus embryo with chlorophylls *a* and *b*. The same solvent as that of Chiba and Noguchi[1] was used for the development of this pigment.

A Diurnal Cycle in the Mitotic Activity of Ascites Tumour Cells in Mice

OBSERVATIONS of a diurnal variation of frequency of mitosis in the normal tissues of the mouse show a diphasic rhythm in the skin epidermis and epithelia of œsophagus, epididymis and duodenal mucosa[1]. On the other hand, absence of a diurnal variation was noted in lymph nodes of the gut and in the semen-producing canals of the testis[1].

A double diurnal cycle in the mitotic activity of different kinds of neoplastic tissue has also been reported for human carcinoma[2] as well as for *ITB*-tumours in rats[3]. The ascites tumour represents a certain type of tumour—a cell suspension implanted in a host animal; thus there is a looser connexion both between the tumour cells themselves and between the tumour and the host animal. For natural reasons the vascularization in ascites tumours also differs from that in solid tumours. It seemed, therefore, of interest to determine whether a mitotic daily rhythm exists also in ascites tumour cells.

As experimental animals we used male white mice, two to three months old and in good health. They were kept under standard conditions in normal daylight, at a constant temperature of + 18° C., and were fed every day at 9–10 a.m. After an adaptation period of at least two weeks under these conditions, the mice were inoculated intraperitoneally with ascites tumour cells of the Ehrlich type. Since we thought that puncturing the belly too frequently for obtaining samples disturbed the daily rhythm of the mice, we started a series of experiments during May 1955 in which samples of ascites cells were taken only twice a day. One sample was taken at an hour which was shifted continuously 3 hr. forward from one day to the next. Another sample was always taken at the same hour every day. The differences in value between these two samples were

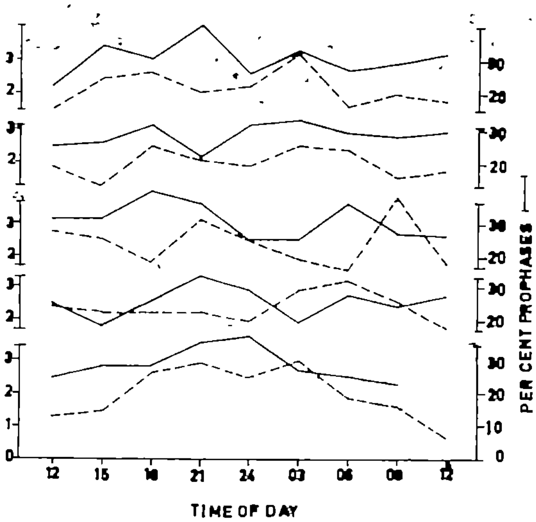

Fig. 1. Daily rhythm in mitotic activity of ascites tumour cells in five mice. Continuous line: prophases (per cent). Broken line: mitoses (per cent)

used as a sequence to give an expression of the daily variation in the mitotic frequency of the tumour cells. The samples taken at a fixed hour showed the ageing of the tumour and demonstrated a maximum in mitotic frequency at 7–10 days incubation. On the same occasions samples of the ear epithelium were taken with the conchotome for comparison. However, in spite of the fact that four series of five mice each were used, the results obtained were not sufficiently uniform. The principal reason for the irregularity of the values must be the fact that a daily rhythm is not firmly fixed to definite hours of the day.

As these series of experiments failed to give conclusive results concerning a possible mitotic rhythm, we tried the other type of experiment taking samples frequently during 24 hr. Surprisingly enough, this treatment did not disturb the daily rhythm. Five male white mice, kept as described above, were used for the experiment. The mice were inoculated on October 25, 1955, and the samples were taken during the twenty-four hours of November 2. Samples were drawn every third hour, fixed and stained by aceto-orcein and examined microscopically as squash preparations, and the mitotic index as well as the amount of different mitotic phases were determined. Every count included 1,000 cells. The results are presented in Fig. 1.

Of the five mice used, the ascites tumour in four of them showed a diphasic mitotic rhythm, with one maximum in the early night and another in the early morning. One mouse showed a single maximum in mitotic frequency—during the night only. In the experimental series with the long-period sampling, only a night maximum could be demonstrated with any certainty for both the ascites cells and the ear epithelia. It may be questioned whether the observed maxima of mitotic frequency actually represent maxima in mitotic activity, when there is no possibility of counting a change in the cell numbers. In such a case it is almost impossible to state whether a maximum in mitotic frequency is the result of actual increased production of cells or of a mitotic inhibition —a prolongation of the time taken by the mitotic stages in relation to the interphase. However, if mitotic maxima coincide with a maximum of prophases, there is a strong indication that cells have been forced out of the interphase stage into the mitotic stage, and thus the mitotic maximum corresponds to an increased true mitotic activity. As can be seen from Fig. 1, the maxima in mitotic frequency coincide in all cases with prophase maxima. Thus it may be concluded that an ascites tumour has a diurnal cycle of true mitotic activity, which is in most cases diphasic. This may correspond to the double diurnal cycle reported for the majority of solid tissues of the mouse, provided that these maxima also represent an increase of cell production.

This investigation was facilitated by grants from the Scandinavian Insulin Foundation.

Teratogenic Effects of Beta-Amino-Propionitrile in the Chick Embryo

The present investigation was undertaken in order to study the possible effects of β-aminopropionitrile on early fœtal development.

Stamler[1] has shown that the feeding of sweet-pea seed meal to pregnant rats during the last six days of gestation induced poor development of mesodermal tissues and fœtal death, whereas the fœtus was not adversely affected if the meal was withdrawn from the diet before the seventeenth day of gestation. These findings have been attributed to changes either in the activity of fœtal mesenchymal tissues, or in placental permeability[1], or in maternal endocrine balance[2]. Thus it seemed necessary to exclude maternal-fœtal interrelations in order to assess the possible effects of β-aminopropionitrile. The chick embryo was therefore chosen as the test organism.

Batches of cross-bred (Rhode Island Red and Leghorn) fertile eggs were treated at different times up to the ninth day of incubation. A single injection of β-aminopropionitrile (0·25 per cent, w/v aqueous solution), varying in volume from 0·05 ml. to 0·4 ml., was made into the yolk sac of each egg. Batches of control eggs were similarly injected with identical volumes of distilled water. Embryos were examined on the tenth, eleventh or twelfth days of incubation.

The results following injections made on the seventh day of incubation are shown in Table 1.

Of the twenty-six surviving embryos in the experimental group, twenty-one were abnormal (Table 1), several abnormalities frequently being present in a single embryo. In all the malformed embryos both tibiæ were bowed, while the mandibles were markedly buckled or bowed in fourteen (Fig. 1). The metatarsus was bowed in one embryo, hæmothorax was

Table 1. β-Aminopropionitrile (0·25 per cent) injected on the Seventh Day of Incubation

Amount injected (ml.)	No. of eggs	Died	Survived: No obvious abnormalities	Survived: Malformed
Controls	24	9	14	1
0·1	18	5	5	7
0·15	35	24	0	11
0·2	16	13	0	3
Totals	69	42	5	21

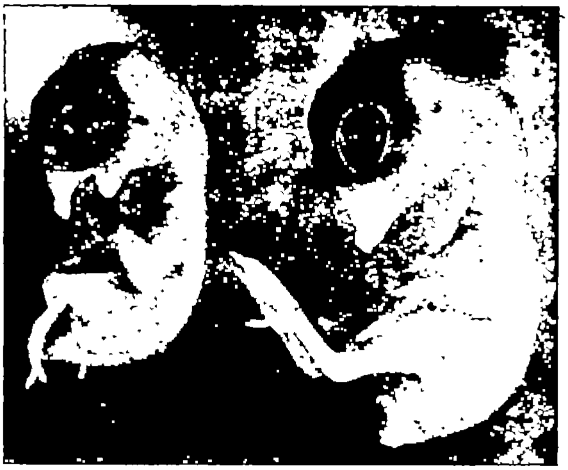

Fig. 1. Left: Ten-day old embryo with stunting, buckling of mandible and bowing of tibiæ induced by 0·15 ml. of 0·25 per cent β-aminopropionitrile injected into the yolk on the seventh day of incubation. Right: Control ten-day old embryo for comparison

found in another, and in a third there was scoliosis of the cervical vertebræ. Œdema of the body wall alone was found in the only abnormal control embryo. It was possible to examine only eight of the embryos that had died—the remainder being far too macerated. All these embryos showed malformed beaks, the majority had hæmorrhages into the amniotic sac and/or hæmorrhages from the vessels of the chorio-allantois.

Embryos dosed with β-aminopropionitrile on the first four days of incubation showed the same abnormalities as those injected on the seventh day, but in addition three had agenesis of the anterior thoracic and abdominal walls.

The pronounced changes in the beaks of chick embryos may perhaps be the counterpart of the mandibular exostoses described in rats poisoned with β-aminopropionitrile[3]. Agenesis of the body-wall in chicks, on the other hand, may perhaps be compared with the abdominal herniæ described in rats on lathyrogenic diets[4].

It is clear, even from the above macroscopic studies, that as in the rat so too in the chick, the mesenchymal tissues are profoundly affected by β-aminopropionitrile. The serial events culminating in the lesions described above require microscopic investigation. So also does the possible existence of lesions in the internal organs and vessels, particularly as studies in weanling rats have shown the aorta to be extremely susceptible to the effects of β-aminopropionitrile.

These investigations are now in progress.

I thank Prof. T. Gillman for his encouragement and advice during this investigation, and Mrs. P. McManus for her skilled technical assistance. This work was carried out with the aid of a grant from the National Cancer Association of South Africa.

Sodium Ions and Tissue Metabolism: Some Metabolic Peculiarities of Brain Tissue

ACCORDING to Hodgkin and Katz[1], in the complete absence of sodium ions from the surrounding medium, the action potential of the giant axon of the squid is diminished, whereas its resting potential is not changed at all. This observation of the effect of sodium ions on the electrical activity of nerve fibre is one of the bases of the sodium theory of nerve activity of the Cambridge school. So the metabolic effect of sodium-free medium on brain slices has been studied[2], with special emphasis on its relation to the functioning of nerve cells in general, because the metabolic activity of nerve fibres is difficult to measure.

We have studied the effect of sodium-free medium on the metabolism of various tissues, with special attention to the metabolic peculiarities of brain tissue, and also the relation between metabolism and sodium concentration.

The experimental conditions have previously been described in detail[2]. In preparing sodium-free medium, sodium phosphate was replaced with potassium phosphate, and sodium chloride with choline chloride in order to maintain the correct osmotic pressure. In the experiments summarized in Fig. 1, sodium chloride in the usual Krebs–phosphate Ringer solution was replaced partially with potassium chloride, and for the complete omission of sodium ions glycyl-glycine buffer was used instead of sodium phosphate buffer. Glucose was determined by the 'anthrone' method, pyruvic acid according to Friedemann and Haugen and lactic acid by the method of Barker and Summerson.

On the complete omission of sodium ions from the incubation medium, the aerobic lactic acid formation of guinea pig brain cortex slices was greatly increased and also the glucose consumption increased. But the oxygen uptake was not altered significantly. The aerobic formation of lactic acid from fructose

* Mean ± standard deviation: figures in parentheses, numbers of experiments. † Glucose was rather increased in the medium.

was also increased to 34·3 ± 0·5 (3) µmol./gm./hr. in the sodium-free medium, the control value of which was only 6·2 ± 0·4 (3) µmol./gm./hr. When lactic acid was used as a substrate, the respiration was severely inhibited and the utilization of lactic acid was not detected. On the other hand, when pyruvic acid was added as a substrate, the oxygen uptake was increased greatly. But the respiration of brain slices metabolizing citrate, succinate, fumarate or glutamate was somewhat inhibited. These effects of sodium-free medium on the metabolism are thought to be peculiar to brain tissue, and are not observed with slices of liver, kidney or diaphragm (Table 1).

When potassium ions were added to the medium, replacing sodium, the oxygen uptake, glucose utilization and lactic acid formation were highest on the addition of 60 m.moles potassium; with further decrease of sodium ions, the metabolism was somewhat reduced. It was found that the ratio of the concentration of potassium to sodium is intimately related to the metabolic activity of brain slices.

These phenomena indicate some metabolic characteristics of brain tissue and the functional specificities of nerve cells. A detailed report on the effect of some inorganic ions, including others beside sodium, is being prepared for publication.

A Non-Destructive Technique for locating Amino-acids

THE electrophoresis of free amino-acids on paper strips by the technique of Durrum[1] results in close discrete bands which are difficult to locate by running parallel pilot substances.

The fluorescence produced by heating the paper at 100° C. for 15 min.[2] proved to be too insensitive for satisfactory location. Heating[2] after immersion in acetone increases the sensitivity, but we have now found that treating amino- or imino-acids with *o*-coumaric acid dissolved in acetone produces a compound which gives a bright yellow fluorescence. The amino-acids can easily be regenerated quantitatively.

Following electrophoresis in 2 *N* acetic acid, the paper strips are dried overnight at room temperature, and then immersed in acetone containing 0·1 per cent *o*-coumaric acid. The lengths of paper are air dried for 2–3 min., warmed in an oven at 100° C. for 1–2 min., and then briefly exposed to ultra-violet light from a Mazda *MBW/U* bulb. The yellow fluorescent amino-acid complex can then be accurately delineated against a background blue fluorescence which rapidly fades due to the heat produced by the ultra-violet lamp. Finger pressure also produces yellow fluorescent areas.

The separate bands of amino-acids can be extracted and then chromatographed by the descending butanol/acetic acid/water (40–10–50) system. The *o*-coumaric acid contamination runs with the solvent front and has no effect upon either the speed of running or upon the separation of the eighteen common amino-acids investigated. After chromatography, the paper sheets are dried overnight at room temperature, and the individual amino-acids located by the fluorescence technique. Under these conditions the sensitivity is such that 2 µgm. of amino-acid/sq. cm. of paper can be detected without difficulty; the lower limit appears to be about 1·2–1·4 µgm./sq. cm. The area of paper containing the amino-acid is cut out and the amino-acid content determined by the pyridine–phenol–ninhydrin method of Troll and Cannan[3].

The excised paper contains less than 30 µgm. of *o*-coumaric acid per sq. cm., and experiments have shown that the colorimetric determination is unaffected by the presence of 300 µgm. of *o*-coumaric acid. Recovery experiments employing the method of location described have given quantitative yields of chromatographed amino-acids, but extending the time of heating at 100° C. to 5 min. will produce losses of up to 10 per cent. For this reason over-exposure to the hot ultra-violet lamp should be avoided.

A Route for Intravenous Injection in the Albino Rat

Drs. Everett and Sawyer[1] claim to have found that the small saphenous vein on the foot of the rat is far more satisfactory than the more commonly used tail vein for intravenous injection.

We, in this laboratory, found even this vessel in the albino rat (200 gm.) to be too small and difficult to use, and have developed the following site and technique to our greater satisfaction; this, also, is on the unanaesthetized rat.

The rat is placed quickly and comfortably into the animal restrainer[2], leaving one hind-limb free (30–40 sec.). The long hairs are then removed from ankle to hip on the posterior surface of the free limb, using electric clippers (10–15 sec.), then wet-shaved (about 30 sec.) to expose the quite large superficial vein—the lateral marginal vein[3].

The rat can be held firmly by an assistant placing the right hand over the hips of the animal, with the free limb passing between the first and second fingers and applying sufficient pressure to cause this vein to become quite prominent without the use of any form of tourniquet. The assistant's left hand holds the foot firmly.

A 27-gauge, ½-in. hypodermic needle is suitable for this vein, though some operators may prefer a 26-gauge.

Intracellular Recording from Spinal Motoneurones following Stimulation of Medullary Pyramids

ALTHOUGH a rich literature is available concerning the anatomy and the physiology of the lateral corticospinal tract, no reports have been published in which intracellular electrodes were employed in studying the synaptic connexions of the corticospinal tract in the lumbar spinal cord. Lloyd[1] used extracellular and ventral root recording, and laid the theoretical groundwork for the present study.

I have now shown that motoneurones are excited by corticospinal impulses in the same manner as that in which they are excited by afferent (orthodromic), antidromic or direct routes of stimulation[2–7].

Glass micropipettes filled with potassium chloride were inserted into cat spinal interneurones and motoneurones, identified according to criteria established by Eccles[3] and Frank and Fuortes[4]. The potentials led off from these cells were amplified and recorded using the technique of Frank and Fuortes[4] in one case and that of Li and Jasper[8] in all the other experiments. Stimulation of medullary pyramids was accomplished by direct insertion of electrodes (platinum or steel, insulated to tip) following ventral neck dissection. All animals were decerebrate. Contralateral limb movement was used for identifying the position of the stimulating pair with respect to the decussation of the pyramids.

The pyramidal tract stimulus (isolated by radiofrequency) consisted in a train of seven to ten square pulses of amplitude 7·5–10·0 V., duration 0·1 msec., at 1·0 msec. intervals. Such trains summated with potentials recorded from a motor neurone in response to dorsal root stimulation, or antidromic stimuli of insufficient intensity to invade the soma, to produce firing of motoneurones. Non-invading spikes following maximal ventral root stimulation were helped to invade the soma by pyramidal stimulation. Small responses to the second of two antidromic shocks within critical stimulus interval[4] were also helped to invade by the pyramidal stimulus. Pyramidal stimulation alone produced graded subthreshold depolarization resembling dorsal root synaptic potential, although shorter in duration. Progressive increase in the strength and/or frequency of such stimulation resulted in the firing of motoneurones. The latency, amplitude and duration of the responses were similar to those obtained by other means. All responses exhibited inflexions in the rising phase of the spike, a finding which presupposes the mode of excitation of the motoneurone by corticospinal impulses to be the same as that found for other routes by other authors[2,7,9].

Thus far in the study, eight interneurones have been penetrated, and the activity of five of them following physiological stimulation (toe-pad pinch) was increased by pyramidal stimulation, while three were inhibited. The patterns of response of the interneurones fell roughly into two groups which will be described elsewhere at length. The implications of these results with respect to corticospinal control of movement will also be discussed elsewhere.

Thanks are due to Drs. Karl Frank, Choh-luh Li, Cosimo Ajmone-Marsan, and Messrs. Saxton Howard and Samuel Cooper for their help in various phases of this investigation.

Differentiation of Somatic and Autonomic Nerve Fibres in Tissue Sections

VARIOUS morphological types of encapsulated and non-encapsulated nerve endings in glabrous skin and mucous membranes have been described by several workers[1,2], and these findings have been confirmed recently in a study of the innervation of selected regions of the oral mucosa in a number of mammals[3]. In contrast, little attention has been given in the past to the nature of the nerve plexuses from which these terminations arise, and the investigation has been extended to include this aspect of the problem[4].

Although the topographical features of the plexuses can be demonstrated satisfactorily using routine neurohistological methods, such as methylene blue and silver impregnation techniques, considerable difficulty has been experienced in distinguishing somatic myelinated fibres from those pertaining to the autonomic nervous system. This can be attributed to the inconsistent results normally obtained by these methods; for in silver impregnation of frozen sections, for example, while one section may show optimal staining for both the axons and the myelin sheaths, succeeding sections may stain quite differently and the distinction between the myelinated and non-myelinated nerve fibres is lost. One is prevented, therefore, from tracing these fibres for other than a short distance in the tissues, and from differentiating between finer branchings of myelinated fibres and those of the autonomic system. In addition, results are governed to some extent by the appearance of artefacts, which even when reduced to a minimum can by no means be discounted. It is thus extremely difficult to establish a set of criteria applicable to all sections in a series.

In an attempt to stain autonomic fibres constantly and selectively a method, first described by Champy[5] to demonstrate sympathetic terminations in or around cellular elements, has been tried with interesting results. It has been claimed[6] that the method is specific for sympathetic endings by reason of their association with adrenalin-like substances, and the technique applied to the innervation of the intestinal tract and various glandular structures, notably the salivary glands[7].

In oral mucous membrane, however, not only are postganglionic autonomic fibres demonstrated as a succession of tiny black beads or fine lines, but also myelinated somatic fibres show in marked contrast well-defined myelin sheaths with nodes of Ranvier. The fibre bundles of which the plexuses are composed are seen to consist of a mixture of both types of nerve fibre, and the perivascular plexuses and terminal nervous network are easily made out. Neither is there confusion between the latter and the fine ultra-terminal branches of the somatic fibres, for these do not appear to stain by this method. The nature of the differentially stained fibres has been confirmed by experiments on animals, preliminary results indicating an extensive anastomosis of the terminal autonomic network across the mid-line, a feature which is being investigated more fully.

In the present work the original staining solution formula has been employed, namely, a block of fresh tissue is immersed in a mixture of osmium tetroxide and sodium iodide for 24 hr. Thereafter instead of embedding in paraffin, as recommended[6], the tissue is washed well in running tap water and stored for several days in 10 per cent neutral formalin before preparing frozen sections. The additional fixation has been found to limit the diffusion of the contents of fat cells, which are heavily stained by the osmic acid, and this limitation is further aided by the use of frozen sections. During mounting the period in xylol is reduced to a minimum, and although some diffusion may persist, it is not sufficient to detract from the clarity of detail, either for microscopic examination or photographic reproduction. In the event of overstaining this can be reduced by alternate immersion in 0·25 per cent potassium permanganate solution and Pal's fluid.

These observations, which are being published elsewhere in greater detail, suggest that this simple technique is a general nerve stain which gives constant results, and may prove a valuable additional neuro-histological tool for workers in similar fields. A limited examination of other tissues by this method, for example, dental pulp and skin, points towards unequivocal results being obtainable.

Attempt to transplant the Œdema Fluid of Experimental Inflammatory Œdema in Rats

According to the literature, the materials suspected of being either the cause of, or an important participant in, the different types of acute experimental inflammatory œdema in animals include histamine, hydroxytryptamine, some peptides (for example, leukotaxine, etc., of Menkin[1]), spreading factors (for example, Duran-Reynals[2], McGovern[3]), the plasma protein permeability factor of Miles and Wilhelm[4], and also certain nucleic acid derivatives (Spector and Willoughby[5]). The presence of at least the first two important members of these substances in œdema induced by testicular extract of the rat's hind-paw was demonstrated by Rowley and Benditt[6] as well as in our laboratory. The histamine activity, for example, ranges from 2 to 10 μgm. in 1 ml. of œdema fluid.

An attempt was therefore made to transmit acute œdema of the rat's hind-paw in sixteen experiments carried out with young rats of 120–150 gm.; œdema was induced by testicular extract or a bacterial hyaluronidase preparation. Details of the method of production and estimation of the œdema induced by testicular extract have already been given[7]. For the bacterial preparation, 'Hyason' (Organon) was used in amounts of 75–150 T.R.U. to 0·1 ml. saline injected. Five to ten minutes after plantar induction, the gross, acute (protein-rich) œdema fluid can be readily obtained by puncture on the dorsal side where the clear fluid appears. After defibrination in a small test-tube with the aid of the puncture needle, 0·1 ml. of the œdema fluid is injected, within 2–4 min., into the opposite hind-paw of the same animal.

The released materials present in the standardized amount of 0·1 ml. of the injected œdema fluid fail to induce noteworthy œdema. On the other hand, the significance of local factors could be demonstrated: a local refractory period (4–8 hr. in our experiments) occurs after the acute inflammatory phase. Although the transplantation was seemingly effective in five out of the sixteen experiments, the presence of the œdema-inducing material was responsible for these positive cases, as demonstrated in controls in which a half or a third of the amount originally injected of testicular extract or bacterial hyaluronidase was able to produce remarkable œdema. The other eleven experiments were negative.

The role of a theoretical inhibitor, present in the œdema fluid as a product of natural defence, was investigated. Amounts of bacterial preparation were dissolved (*a*) in the œdema fluid and (*b*) in saline, and were then injected simultaneously into the two hind-paws of the same animal. No difference was observed between the response of the two extremities in three experiments.

Substances released after the injections are obviously involved in the production of œdema, but the presence of certain amounts of exogenous œdema-inducing material is necessary to produce 'regular' œdema, despite the fact that released substances are present in the possible endogenous form and concentration. In fact, if the presence of injected œdema-inducing material were unnecessary, and the liberated endogenous substances could act alone, then we could expect that œdema fluid would be continuously transmissible. As we have shown, this is not the case. All the substances mentioned in the first paragraph could perhaps become 'œdema-inducing' if they were administered in excess amount or in excess volume. Naturally, there are species differences.

I suggest, therefore, that the production of œdema in the rat's hind-paw, at least, is a primary function of the currently used œdema-inducing substances.

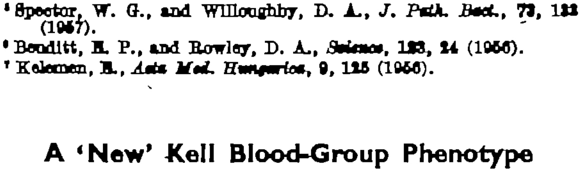
A 'New' Kell Blood-Group Phenotype

During the past year or more, Dr. Fred H. Allen, jun.[1,2], of the Blood Grouping Laboratory, Boston, has opened up the Kell blood-group system through the discovery of two antibodies additional to anti-K and anti-k, called anti-Kp^a and anti-Kp^b, which unquestionably define antigens in the Kell system. The former, he tells us, reacts with about two per cent of random bloods, while the latter reacted with all but 2 of 5,500. All bloods tested reacted with at least anti-K or anti-k and one of the new antibodies. In order to facilitate further investigation of the Kell system, Dr. Allen supplied certain laboratories, of which ours was one, with samples of these two antibodies. Having these to hand allowed us recently to define a new Kell phenotype, namely, K−, k−, Kp(a−b−), in two sisters. The Kell phenotypes of the family are as follows:



These have been confirmed both in Dr. Allen's laboratory and in that of Drs. Race and Sanger. The family is of Polish extraction. The parents are second cousins.

The propositus had been transfused in 1952; her blood contains antibodies of the Kell system, the exact specificity of which we have not yet been able to determine; her baby, born in 1957, suffered from hæmolytic disease of the new-born due to these antibodies, while she herself, given a bottle of K+, k+, Kp(a−b+), and a bottle of K−, k+, Kp(a−b+) blood, suffered a severe reaction with jaundice and oliguria. Her K−, k−, Kp(a−b−) sister was transfused in 1954; she has no Kell antibodies. At the time of the original transfusions, namely, in 1952 and 1954, each sister received blood from two donors; all four donors are K−, k+, Kp(a−b+).

The 'new' phenotype is put on record to further the study of the make-up of the Kell system.

Differences in the Food of the Young and the Adult Indian Mackerel, *Rastrelliger kanagurta* (Cuv.)

The problem of the food of fishes with its varied bearings on their shoaling habits and migrations has engaged the attention of fishery biologists since the beginning of the present century. The mackerel is an important food fish in both hemispheres. Several contributions[1-5] have been made to our knowledge of the food of the Indian mackerel, *Rastrelliger kanagurta*, which contributes to one of the largest fisheries of India. All these observations, except those of Chacko[3], which are from the Gulf of Manaar, are confined to the west coast of India. According to these workers, mackerel is a noted plankton feeder, securing its food by filtration. Chidambaram[2], while observing the adult mackerel as plankton feeder, suggested the carnivorous habits of the young mackerel. Later, in a detailed account on the food of this fish, Bhimachar and George[4] observe that "the food of the young mackerel does not radically differ from that of the adult". Pradhan[5] has arrived at a similar conclusion regarding the food of mackerel; but one will not fail to note from his observations that young mackerel less than 89 mm. in total length are not represented in his material.

In the course of the present investigation, extending for more than a year, 593 mackerel belonging to all sizes ranging from 32 mm. to 243 mm. in total length have been collected from the Lawson's Bay landings near Waltair, and their food contents examined. From this analysis it became evident that mackerel of the size of 90 mm. and more in total length are plankton feeders, consuming large quantities of Protophyta (phytoplankton) along with some zooplankton. Further, it was noted that the adult mackerel is not an indiscriminate feeder. Though the proportions of the phyto- and zoo-planktonic elements in the stomach contents of this fish are more or less in accordance with their relative abundance in the plankton, a sort of selective feeding (avoidance) exists at least with regard to such macroplanktonic forms such as medusæ, ctenophores, salpæ and

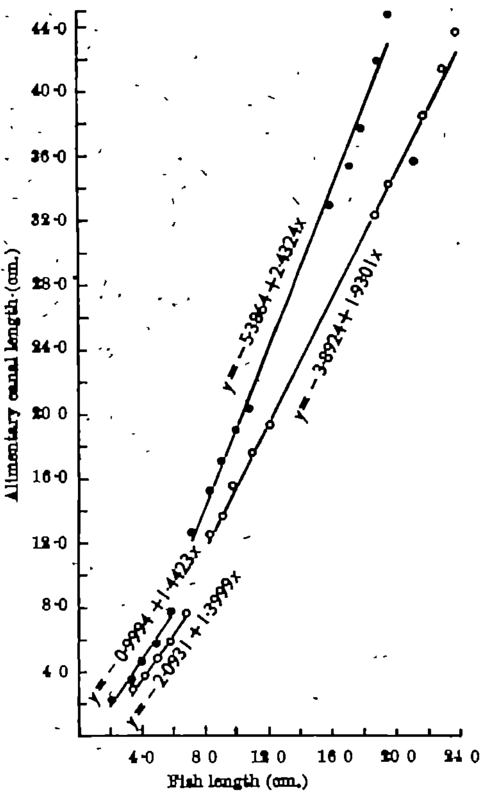

Fig. 1. Number of fish measured, 575; all measurements were grouped at 1-cm. class-intervals and each point represents the average value for each 1-cm. class. The straight line in each case represents the best fit as calculated from the equation given alongside.

Standard length against alimentary canal length, —●—●. Taking the first five values as normal (that is, $y = -0·9994 + 1·4423x$) the difference in slope between the first five and the remaining ten points is significant at the 5 per cent level of χ^2 for nine degrees of freedom.

Total length against alimentary canal length, —○—○. Taking the first five values as normal (that is, $y = -2·0931 + 1·3999x$) the difference in slope between the first five values and the remaining eleven points is significant at the 5 per cent level of χ^2 for eleven degrees of freedom

chaetognaths. In the stomach contents of mackerel of size-range 90–243 mm. total length, relatively little zooplankton was found and this consisted of the following forms: copepods, larval cirripeds, larval pelecypods, *Lucifer*, *Evadne* and larval crustaceans.

The food habits of juvenile mackerel ranging in total length from 32 to 90 mm. are different. The stomach contents of these juvenile fish showed that fish larvæ (*Anchoviella* species) form their staple food, and this is supplemented by the planktonic sergestid, *Lucifer*. In rare cases, copepods and a few Protophyta were noted in the stomach contents. These observations suggest that the juvenile mackerel are carnivorous and selective in their food habits.

While making biometrical studies on some marine fishes of the Waltair coast, we have observed an allometric growth in the alimentary canal of the mackerel. The relationship between the linear measurements of the alimentary canal and total and standard lengths of the mackerel is plotted in Fig. 1. It is clear from the graph that the relative length of the digestive tract is greater in the adult fish than in the juveniles. It is interesting to note that both the change in the food habits[5] of the fish and the relative length of its alimentary canal take place at the same total length of fish. It is very likely that this change in the relative length of the alimentary canal of the mackerel is associated with the change in the food habits of the fish at about 90 mm. total length.

We thank Mr. K. Krishna Rao for his help in the statistical treatment of the results presented here.

Quantal Responses to Mixtures of Drugs

THE joint action of two drugs can be termed 'non-interactive' if, when applied together, neither modifies the physiological action of the other that leads to the response under consideration[1]. We have previously formulated the relation between dose and quantal response for the extreme forms of this type of joint action, namely, simple similar action[1], in which the drugs act on the same physiological system, and independent action[1,2], in which they act on different systems. The relation for independent action allowed different degrees of correlation of the tolerances for the respective drugs; but the relation for simple similar action allowed only their complete positive correlation. We have now extended this work, first to cover types of non-interactive joint action intermediate between the extreme forms, and secondly, to permit any degree of correlation of tolerances for every form of non-interactive joint action. Since interactive joint action can be formulated as a generalization of non-interactive[1], the whole theory of quantal responses to mixtures of drugs is thereby unified.

Our new general approach to the problem is to infer the conditions for non-response in the individual organism for every form of non-interactive joint action, and not as before to do this for independent action only. An outline of the more important results of this approach is given below, and details of the investigation will be published elsewhere.

Suppose that the relations between dose and response for the individual drugs are

$$x_1 = \epsilon_1 + \theta_1 \log \omega_1 \qquad (1)$$

and

$$x_2 = \epsilon_2 + \theta_2 \log \omega_2 \qquad (2)$$

where ω_1, ω_2 are the amounts acting physiologically, and x_1, x_2 are normal equivalent deviations. Let q be the proportion of organisms failing to respond when the drugs are applied together. The integrated bivariate normal distribution, with correlation coefficient ρ, gives a general equation for non-interactive joint action, namely,

$$q = \iint_R (2\pi)^{-1} (1 - \rho^2)^{-\frac{1}{2}} \exp[-(u^2 - 2\rho\, uv + v^2)/2(1 - \rho^2)]\, du\, dv \qquad (3)$$

where R is a region defined by

$$h^{(\epsilon_1 + u)/\theta_1} + \nu h^{(\epsilon_2 + v)/\theta_2} < 1 \qquad (4)$$

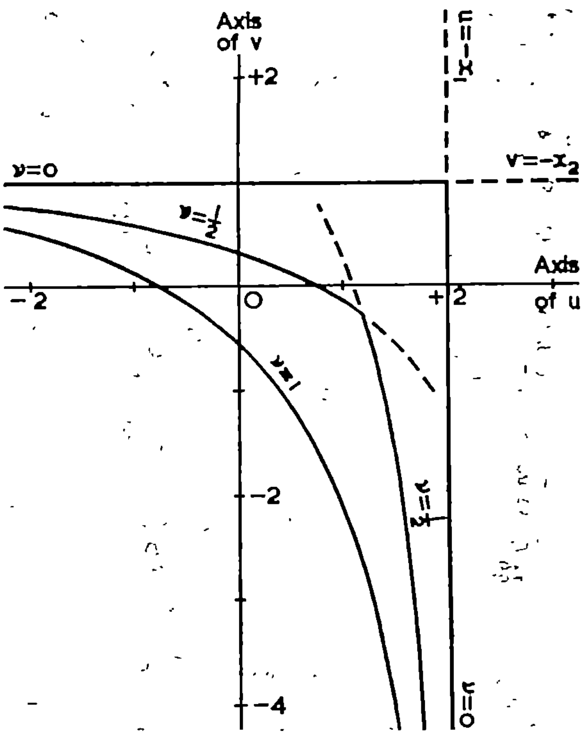

Fig. 1

and

$$\nu h^{(x_1+u)/\theta_1} + h^{(x_2+v)/\theta_2} < 1 \qquad (5)$$

Here h is the base of logarithms and ν is a parameter, ranging from 0 to 1, measuring the degree of similarity between the physiological actions of the two drugs. When $\nu = 0$, (3) is the equation for independent action that we obtained before; when $\nu = 1$, it is the equation for simple similar action.

Fig. 1 shows in plan exemplary regions of the bivariate normal surface defined by (4) and (5), and is comparable to a figure we gave before[2] to illustrate the regions for independent action. For Fig. 1, $x_1 = -2$, $x_2 = -1$, $\theta_1 = 4{\cdot}5$, $\theta_2 = 8$ and $h = 10$. The boundaries of integration are the continuous lines marked with the corresponding values of ν, namely, 0, ½ and 1. The regions of integration lie to the left of and below the boundaries.

In the special case in which $\nu = 1$, and $\rho = +1$, (3) becomes

$$h^{(x_1-x)/\theta_1} + h^{(x_2-x)/\theta_2} = 1 \qquad (6)$$

where x is the normal equivalent deviation corresponding to $1 - q$. The equation that we put forward previously for simple similar action was (6) with the restriction that $\theta_1 = \theta_2$. Equation (6) with $\theta_1 \neq \theta_2$ accounts for some data[3] on the joint action of certain insecticides closely related chemically.

Homoserine in Bleeding Sap of Pea Plants

In a recent paper[1], it was shown by means of paper chromatography that in bleeding sap of pea plants 5½ weeks old, inoculated with effective strains of *Rhizobium*, some amino-acids and amides occurred. The chief of these compounds proved to be aspartic acid, asparagine, glutamine and a substance giving a colour with ninhydrin, of which the R_F values on nearly all chromatograms corresponded with those of threonine. Only when using phenol/water as solvent was a somewhat higher R_F value found. The other solvents used were: collidine/water; butanol/acetic acid/water; propanol/water[2].

In an attempt to identify the spot, the following solvents were used: 'Methylcellosolve' (ethyleneglycol monomethylether)/water[3]; methanol/water/pyridine[4]; *tert.*butanol/methylethylketone/water/diethylamine[4]. Of these three solvents, only the latter produced for the unknown substance an R_F value deviating from that of threonine, as phenol/water did.

By comparing a mixture of known amino-acids (including homoserine) with the substance on the chromatograms, and by adding homoserine to the bleeding sap before running the solvents, the unknown spot was finally identified[5-9] as homoserine (an isomer of threonine).

This homoserine was found for the first time in 1953 by A. I. Virtanen and co-workers[5,6] to be one of the principal free amino-acids (70 per cent ethanol-extract) occurring in pea plants. Later on it was found by Virtanen and co-workers[7] to occur as such also in other plants (even in non-legumes) although in smaller quantities.

The procedure described above proves that for chromatographical identification of amino-acids in fluids of unknown composition, it is imperative to determine R_F values in several different solvents (five at the least), before deciding upon the identity of a spot.

Abnormal Metamorphosis in Saturniid Moths Infected by a Microsporidian

DEVIATIONS from the normal course of metamorphosis in insects may be caused by parasitic infections[1,2]. In studies on a microsporidian of the genus *Nosema*, found in *Hyalophora* (*Platysamia*) *cecropia* and afterwards sub-cultured in *Antheraea polyphemus* and *A. pernyi*[3], seventeen of the many infected animals failed to metamorphose normally. The most severely affected were adults of *H. cecropia*. They retained a number of pupal structures. The tip of the abdomen and the genitalia were pupal in form; the cuticle of the rest of the abdomen and of the thorax was a mosaic of pupal and adult types and at the base of each eye was an unpigmented band. Such abnormalities can be produced experimentally by introducing active corpora allata or juvenile hormone (neotenin) into the developing adult during the period when its own corpora allata are inactive[4,5]. Lesser effects were seen in two *A. pernyi* pupæ that had been formed from infected larvæ. Each had white, larval-type setæ scattered over the abdomen, and crotchets in the position of the larval prolegs. Finally, there were adults of both species of *Antheraea* which had patches of pupal-type cuticle.

The results have shown that the parasite apparently upsets the endocrine balance in the host and this leads to a repetition of structures at metamorphosis. Similar effects were produced by Piepho[6] in *Galleria* and by Wigglesworth[7] in *Rhodnius*. They obtained localized repetitions over the sites of implanted corpora allata. Williams[5] has shown that adult male *H. cecropia* have stores of corpus allatum hormone in most tissues of the body, but in highest concentration in the abdomen. Perhaps tissues damaged by parasitic invasion release their hormone. Our *Nosema* sp. is often very unevenly distributed in the host, and although it is primarily a parasite of gut epithelium and a muscle, it will invade silk-glands, fat-body, Malpighian tubules, pericardial cells, brain and nerve-cord. Host cells become hypertrophied and their nuclei begin to disintegrate though the latter are never actually invaded. Later, the cell walls may break down.

Williams[5] could find no juvenile hormone in adult females of *H. cecropia* or in adults of either sex of *A. polyphemus*. In our experiments both sexes of all three species have been metathetelic. Two *A. polyphemus* adults were almost as severely affected as the *H. cecropia*, but most of the *A. polyphemus* and all the *A. pernyi* were only slightly affected. Williams could extract the hormone in appreciable amounts from the abdomen only. In our experiments the abnormalities shown by the *A. pernyi*, which is the least responsive species, were confined to the abdomen. A possible explanation is that there is a decreasing concentration of juvenile hormone in the tissues of the three species in the following order: *H. cecropia* → *A. polyphemus* → *A. pernyi*.

It would appear from Williams's results that there is also a difference between sexes, but we have seen no indication of such a difference. If our hypothesis is correct, it means that the microsporidian is a more sensitive indicator of juvenile hormone than Williams's methods of extraction. An obvious objection to our explanation is that the corpora allata were present in the experimental animals. However, in view of the very localized effects, it is unlikely that the corpora allata were simply over-active. An experiment to settle this doubt would be the removal of corpora allata, followed by infection with the microsporidian. One metathetelic adult has in fact been produced from such an allatectomized pupa, but we cannot draw any conclusions from an isolated result. We put it on record because it is unlikely that further experiments can be carried out in the immediate future.

We have succeeded in infecting *Saturnia pavonia*, *Arctia caja*, *Cerura vinula*, *Selenia bilunaria*, *Sphinx ligustri*, *Pieris brassicae*, *Vanessa io* and the blowfly *Calliphora erythrocephala*, but none of them showed these disturbances of metamorphosis.

We are grateful to Prof. Carroll M. Williams for letting us have the original infected *H. cecropia*.

Vernalization of Green Plants of a Winter Wheat

SPRING cereals differ from winter cereals in their ability to initiate ears immediately under a favourable day-length, without cold treatment of the seed. Unvernalized winter cereals will eventually initiate ears, but even under the most favourable conditions this has not been found to occur until 6–8 weeks after planting[1]. 'Vernalization' or cold treatment of the just-sprouted seed before planting will eliminate this period of delay before ear initiation, and field studies certainly suggest that the growing plant is also capable of responding to cold treatment during this period[2–5]. However, direct evidence of the response of the green plant of the winter cereal to cold treatment is scanty. (Possibly Gunar and Krastina[6] have evidence on this point, but this is not clear from the abstract available to me.)

A previous attempt[7] at cold treatment of seedlings of 'Petkus' winter rye had suggested that vernalization of the green plant might not be possible, but these experiments were carried out at very low light intensity; therefore, in 1955, using a controlled environment cabinet, the experiment was repeated, using whole plants of various ages of an Australian winter wheat, Winter Minflor.

Plants aged 2–44 days, previously grown at greenhouse temperatures never falling below 12° C., were treated for 48 days at a temperature of 3° C. (± 1·5°). Control plants were retained in the greenhouse. Continuous light, which is the most favourable regime for eventual flowering of unvernalized winter rye[1], was maintained for both treated and control plants throughout. Growing points were dissected before and after treatment (Tables 1 and 2). By the end of the period of cold treatment the oldest control plants (99 days) were already beginning to initiate ears, without having experienced any low-temperature treatment. All other plants were completely vegetative, the apices of the cold-treated plants being consistently shorter than those of the controls (Table 1). The increase during treatment of the total number of primordia present on the main shoot is shown in Table 2. The cold-treated plants grew more slowly than the controls, and older plants more slowly than younger ones under both treatments. The longer apices and greater number of primordia of the oldest set of controls is due to the rapid increase in growth-rate of the apex after initiation[1].

THE ARTIFICIAL EARTH SATELLITE

THE fact that the U.S.S.R. has been the first to launch successfully an artificial satellite cannot enhance Russia's political prestige, for fundamentally politics had nothing to do with this scientific achievement. We have no reason for believing that Russian politicians are any more scientifically trained than they are in the West. Neither does this brilliant piece of technology necessarily enhance the status of Russian scientists in the world of science, except perhaps among those who subscribe to the worship of priority in the world of scientific discovery. Moreover, reports that some people in the Western democracies, especially the United States, are expressing fear for the future of world peace as a consequence of this recent news should be treated with the contempt that it merits. This hysterical reaction is a clear symptom of the disease of lack of appreciation of scientific knowledge or its significance, from which many people are suffering to-day.

Apart from demonstrating the efficiency and high standard of scientific research and technical achievement in the U.S.S.R. (a demonstration unnecessary to men of science, but possibly of use to many ill-informed politicians), the most significant feature of this incident is that it reveals how much Russian scientists enjoy financial support, privilege and prestige to a degree much higher than is accorded to their colleagues in most of the democratic countries.

It is not good for science in general that the Russian achievement should be looked upon as a political set-back for the West; neither should it be credited to the U.S.S.R. that she has won a race against the United States. Science flourishes in an atmosphere of encouragement and respect; racing for priority does little or no good. The search for the truth in its own materialist way should be the main objective of science; that is, dispassionate discovery. But in an age of science and technology our men of science must play a more active part in controlling and guiding the social applications of their work. This cannot be done while men of science are treated by too many people in authority as hens in a battery—producing 'eggs' for the use of other people and with little or no say in their disposition.

Accusations have already been made against Western politicians and Service authorities that they have impeded scientific research. This may well be true. It is certainly true that Service 'brass hats' tend to condescend to scientists, sometimes even treat them with contempt; this is due to their lack of knowledge of science. (It is reported that on hearing the news of the Russian achievement, one senior man in the Services retorted that anybody could launch a hunk of iron into outer space. A member of Parliament commented: "If the Russians like to squander untold millions of pounds on moonshine, then that's their funeral". The sincere man of science is dedicated to his work, and in such a vocation encouragement and, above all, respect must be accorded to him by all and sundry. This cannot be, however, in a community where the attitude towards science is one of using it as a tool for political and diplomatic intrigue. Neither can men of science be expected to give of their best when they are treated with condescension or are controlled by people who do not understand what they are controlling.

Often enough recently we have listened to pleas that men of science, especially those in industry and government concerns, should be able to see clearly before them a seat in the board room or among the hierarchy of councils; and, indeed, some of our most successful industrial firms now ensure that the scientists on whom they depend so much shall be offered all the prospects that any other efficient man may reasonably expect.

But among the lay public, this attitude is still very much lacking. Indeed, there are still too many people prone to condemn the scientists for all the world's ills and far too many who openly boast of their lack of knowledge of science and its social applications. It should be no cause for wonder that there is a shortage of scientists or that there is so much apathy and lack of interest in things scientific in any community where the most important schools are encouraging the majority of their best scholars to take up politics, diplomacy, business, etc., or even enter the Church, with a background of political history, economics and the arts but with little or no training in scientific method or appreciation. Perhaps the democratic countries, especially Britain, will show signs of improvement and ability to take their lead in world affairs when the superior attitude of politicians and Service authorities is undermined or modified, when more headmasters in our schools are expected to be trained scientists rather than historians and classicists, and, above all, when the public and the popular Press ceases to look upon scientists as (to use the all-too-common ugly appellations) 'back-room boys' or 'boffins'.

There is no such thing as communist science as distinct from capitalist or democratic science; but there are Russian scientists, and some of them are to be congratulated on this recent brilliant addition to knowledge and achievement. In other countries it might now well be conceded that men of science should be given every conceivable encouragement, which includes higher status and respect; and those States which subject scientific research to false economies should deeply ponder the wisdom of such a policy. (See also p. 734 of this issue.)

THE BALANCE OF GOVERNMENT SCIENTIFIC RESEARCH IN BRITAIN

THE forty-first annual report of the Advisory Council for Scientific and Industrial Research (see p. 726 of this issue) is the last to be prepared under the arrangements for administering the Department which ended with the coming into force of the Department of Scientific and Industrial Research Act, 1956. It follows the pattern of recent years, and time will be required to show whether in fact the new Executive Council will prove a more effective instrument than the advisory body it has superseded. Comments in the present report show how fully aware the Advisory Council was of the difficulty of selecting the most profitable programmes on which the available resources can be employed. As the Advisory Council reminded the Chemistry Research Board, the Department has not, and probably never will have, sufficient resources to carry out all the research work which might with advantage be undertaken. An executive body may be better equipped to terminate investigations which have lost their original importance: it is by no means certain that it will be any the better able to select the best projects or to discriminate soundly between the various projects or activities.

Nor is it certain that an executive body can contribute more decisively to the critical problem of securing that adequate resources are continuously at the disposal of the Department. The Advisory Council, in the present report, in admitting that as a Council it is only concerned with a relatively limited field and is not in a position to judge the relative strengths of claims for Government expenditure, or for the nation's scientific man-power, on civil and on defence research, seems to lean over backward in toning down a passage in last year's report. It now comments that, while the Council has pressed the claims of the Department's work upon the Privy Council, it is discontented rather than intensely satisfied with a situation which is easily remediable by the allocation of additional resources. It deplores the slowing down of the Department's programme of planned expansion caused by the reduction of £150,000 in the Department's estimated net expenditure for 1956–57, and urges very strongly the very early resumption in full of the Department's building plans; but it does not point out sufficiently strongly the serious effect of such interruptions in the work of a scientific department.

What needs to be emphasized is that Britain may have to pay a very high price indeed for the interruption to a planned scientific programme by economies that are in themselves relatively trifling. The benefits to be reaped from the Department's expansion are long-term in character and not available for some time after the planned expansion is complete. Only something much more serious than is disclosed in the Advisory Council's report can justify the interruption in that expansion necessitated by the reduction in the Department's own vote, the postponement of its building projects and the reduction in the provision in the Ministry of Works votes for services to the Department. Once the planned expansion is approved, the resources for its completion should be made available and secure against anything except the gravest of national emergencies.

The position and authority of the Lord President of the Council, as the Minister generally responsible for the supervision, if not co-ordination, of the scientific effort of the nation, and more especially its research effort, are involved in this matter. That responsibility has been somewhat curtailed by the transfer to the Prime Minister on April 2, 1957, of his functions with regard to nuclear energy by an order made under the authority of the Ministers of the Crown (Transfer of Functions) Act, 1946. The same point arises, moreover, in respect of three other matters which are discussed by the Advisory Council in this report.

The first of these is that of the various kinds of scientific grant made by the Department, in which several changes of policy have been made during the year. Hitherto, the Advisory Council has been advised in regard to these schemes by its Scientific Grants Committee and its Nuclear Physics Committee. The scope of the Department's Special Research Grants scheme is now being extended to cover grants for the purchase of special equipment when it is required for the efficient conduct of a general line of research by a team deserving of special support and not only, as now, when it is required for a particular research project of exceptional timeliness and promise. Moreover, the Department is now to take over the responsibility for making postgraduate awards in science and technology made at present in England and Wales by the Ministry of Education and the local education authorities.

The responsibilities arising from this decision will be greater in view of the expansion in scientific and technological education on which the Government has also decided, and, like the extension of the scope of the Special Research Grants Scheme, their efficient administration requires close co-operation with the universities themselves. The Scientific Grants Committee has already undertaken a thorough review of its selection procedure for maintenance awards, and in doing so entered into close consultation with the Committee of Vice-Chancellors and Principals. The Advisory Council believes that in consequence a procedure has been worked out which should not only give satisfaction both to universities and other institutions and to individual applications, but should also make the best use of the time of the members of the Committee and the other scientists who assist the Department in this task.

This review strengthened a growing opinion that the existing division between a Scientific Grants Committee and a Nuclear Physics Committee was not the most suitable arrangement under current conditions, and the Council decided accordingly to separate responsibility for the maintenance allowance and senior research award schemes on one hand from that for the scheme for special researches, including nuclear physics research, on the other, and to set up in place of these two committees a Postgraduate Training Grants Committee and a Research Grants Committee. The decision is obviously sound, if only because it should promote the apportionment of research effort between the different fields. It is the high cost of nuclear physics research which has led the universities to look to the Department for assistance in this field. As the Advisory Council remarks, the heavy and largely unpredictable cost of running large machines for accelerating nuclear particles has made it difficult to provide for them from the universities' quinquennial budget; but although the Department has made an exception to its normal practice of limiting grants to the initiation of research, the position has been reviewed, again after discussion with the University Grants Committee. The Department will continue to provide support on a year-to-year basis, but the support will be limited to the maintenance of the machines and the provision of technicians and cost of electric power, cooling water and refrigerants required to produce a beam of particles.

Here again we see how closely in practice the work of the Department touches that of the University Grants Committee, and the importance of ensuring that at some point in the national administration it should be possible to obtain a conspectus of the distribution of the nation's research effort and of the resources available. It would appear, for example, that this year it has only been possible to make all the scientific grants, recommended by the Councils' two committees as justifiable on account of their timeliness and promise, because of savings on activities elsewhere in the Department. Further, since the Lord President's office is exceptionally well placed to obtain the necessary conspectus of resources, it would seem more logical to extend his responsibilities rather than curtail them. Nuclear research, for example, may well be even more closely interlocked with the research work of the universities, as well as with industrial research, as the development of nuclear energy proceeds, and no review of the national research effort and resources can ignore what is being done by the Atomic Energy Authority.

This is a matter which could well engage the attention of the new Council, though the prime responsibility lies higher up. There is, however, another aspect with which the Council should be closely concerned. One of the Department's major grants was £230,000 to the University of Manchester towards the cost of the radio telescope under erection at Jodrell Bank and of the current programme of radio-astronomy. Now it is learnt that the estimate of £439,616 in May 1953 is likely to be exceeded by more than £250,000. This project is regarded as of such scientific importance that the Advisory Council has recommended a further Government grant of up to £130,000 to help meet this deficit; but in the meantime the Public Accounts Committee has strongly criticized the lack of control of this expenditure.

This is not the place to discuss the matter in detail, but it does illustrate a major difficulty in scientific projects in a rapidly developing field. Fine judgment is required if full advantage is to be taken of continuous scientific advances which are made during the progress of a building project extending over the better part of a decade; but the Department of Scientific and Industrial Research is criticized quite reasonably for not watching the actual expenditure more closely. The Committee of Public Accounts makes the sensible recommendation that, in future, when Government departments entrust substantial grants to universities for specific purposes, they should seek the advice of the University Grants Committee on such matters as definition of contracts, establishment of university sub-committees responsible for the execution of the project and any other measures necessary to control and supervise capital expenditure.

This recommendation seems to indicate that this lapse has not stimulated fresh criticism of the University Grants Committee itself. On the contrary, earlier in this same report, the Committee of Public Accounts, commenting on the Treasury Minute of January 31, 1957, and welcoming the extent to which the Treasury has sought to meet its wishes in regard to non-recurrent grants to the universities, recommends that the new arrangements for control of the expenditure of such grants should be given a three-year trial. It is to be hoped that the argument which the Committee of Public Accounts has maintained for a full decade has been brought to a satisfactory issue without invading university autonomy. It might, however, be well worth while for the new Council for Scientific and Industrial Research to give some attention both to this question of accountability generally, as well as to its own relations with the universities, and to the allied question of ensuring that expenditure on scientific projects once sanctioned is not liable to reduction by passing calls for economy in general.

The other two matters also both relate to the disposition of the Department's resources. The Department has now been made responsible for the National Science Lending Library and is to take over the administration of the nucleus scheme. The Advisory Council agrees that such responsibility can appropriately be given to the Department, but it rightly points out that the development and maintenance of such an institution should not be expected to fall on the Department's present resources for research. There is no indication that the Government has as yet allocated any resources for the new library, nor does the Advisory Council refer to the related matter of a National Reference Library for Science and Technology, which was no less strongly recommended by the Advisory Council on Scientific Policy. The two projects are intimately related, and unjustifiable squandering of precious resources is inevitable if both projects are not planned and developed simultaneously, or indeed if they are not planned as part of a Science Centre.

The exchange of an advisory for an executive body will scarcely be worth the effort if the new Council is unable to make strong representations to the Government on the futility of such parsimony, or to direct attention to the great advantages which will result from prompt action on the recommendations of the Advisory Council on Scientific Policy. Although the advice of the latter body has so far been disregarded, the new body could urge a fresh point of view on the Government, and is at least entitled to protest, alike at the failure to provide the Department with the resources required for the scheme now approved by the Government and at the waste inherent in the Government's proposals. Already, as this report shows, the preliminary planning is making some demands on the resources of the Department's Intelligence and Information Division, although the Russian Literature Centre which it is proposed to create as the first instalment of the National Science Lending Library appears to be in line with recent activities of that Division.

A large proportion of the work of that Division is now concerned with social and economic matters, such as human factors in industry, automation and the study of industrial operations; and the reference to social and economic research in the Advisory Council's report raises the question of the apportionment of the Department's resources in that field, as distinct from industrial research in the usual sense of the word or research in the physical or biological sciences, pure and applied, with which for long the Department was exclusively concerned. The bearing of such effort on industrial productivity is not questioned, but it would be appropriate to have some picture of the national expenditure in this field; there is no clue in the Department's report as to the magnitude of even its own expenditure in this connexion. Some of the work is obviously being done by the research associations, but although it may be difficult to gain an exact idea of the total effort, some approximation is obviously desirable. It is scarcely dignified for it to be unknown, in view of the help that has come from the United States under Conditional Aid; and the termination of that Aid in 1956, to which the Advisory Council refers, makes it the more desirable to estimate the magnitude of our effort, if only as a basis for judging the soundness of the Advisory Council's proposals for further investigations both on human relations in industry and on individual efficiency in industry. The Advisory Council has already reviewed the position and suggested discussions with the Medical Research Council, which was jointly responsible for setting up the two committees. It has also appointed a Committee on Economics and Industrial Operations, with Prof. E. A. G. Robinson as chairman, to keep under review the work in progress in the Economics Section and Industrial Operations Unit of the Headquarters Intelligence Division, to examine current and future requirements covering the general study of industrial operations and the economic factors affecting productivity, research and the application by industry of the results of research, and to make recommendations for work in these fields to be undertaken or supported by the Department.

This is a large question on which the new Council clearly must take early decisions as to general policy and programme; but the time appears to be ripe for consideration at a higher level of the nation's effort in this field and how far it should fall within the scope of the Department. A strong case could be made for entrusting the responsibility for social and economic research to an independent body, in the same way that medical research is the responsibility of the Medical Research Council and agricultural research of the Agricultural Research Council. This is not to suggest that the Department should not undertake such research: it is too closely interlocked with the broad question of productivity and of ensuring the effective utilization of the results of scientific research for a sharp distinction to be made. Nevertheless, some caution and forethought appear to be called for, just as they are in the field of education, to which also the Department makes an important contribution, notably through the research associations.

There is, of course, a considerable variation between the research associations in this respect, which in turn is reflected in their varying status and their experience in obtaining support from the industries they serve. Nor is it simply a matter of whether the industry has its own tradition or practice of research, or whether it tends to lean heavily or exclusively on the research association. The education of an industry in the application of science does not proceed simply through the supply of research results or of trained scientists—the latter being an important aspect of the research associations' contribution to higher technological education. It is a matter also of the staffing of the industry at its higher levels with men competent to assess the significance of scientific and technical advances for the processes and products of the industry—a matter which goes far beyond the supply of information or of scientists and technologists.

What is increasingly essential is that a continuous review of the functions of the Department should be undertaken in relation, not simply to the country's effort in research generally, including medical and agricultural research as well as university research and social and economic research, but equally to its contribution to technological education, the training of scientific and technical man-power, and information services, productivity and the like. For this task the Lord President of the Council and his office occupy a key position, as appears from a survey made by a study group of the Royal Institute of Public Administration recently published under the title "The Organization of British Central Government, 1914–1956". The chapter on scientific research in that volume brings home, however, just as emphatically as the valedictory report of the Advisory Council for Scientific and Industrial Research, that the overriding need of the moment is for some authority competent to hold in broad review the nation's effort in these varied but related fields, to assess the significance of the recommendations of the various councils and to keep the distribution of the available resources in balance with the varied needs; it must also be strong enough to present the claims so that they receive full consideration in relation to those of defence, social services and the other sectors of the national life. Much of this could be done by the Advisory Council on Scientific Policy or through the Lord President if the existing powers and responsibilities were discharged in their entirety. On the evidence of the present report from the Department of Scientific and Industrial Research, it can no longer be pretended that the existing arrangement is satisfactory. While the activities of the new Executive Council for Scientific and Industrial Research will be followed with interest and goodwill, it is clear that the Department cannot be expected to make its full contribution to the national welfare and to industrial advance unless this lacuna is made good. There should be, at Cabinet-level, the means for assessing accurately the Department's work in relation to other effort calling for scientific and technical resources, competent to secure a reasonable balance, and strong enough to ensure that the resources made available for such effort are both adequate and undisturbed.

DEVELOPMENT OF INDUSTRIAL CHEMISTRY

A History of Industrial Chemistry

By Dr. F. Sherwood Taylor. Pp. xvi+467+22 plates. (London: William Heinemann, Ltd., 1957.) 30*s.* net.

To give an outline in moderate compass of the origin and development of industrial chemistry is a formidable task, entailing a balanced survey of a vast and complicated field in which pure chemistry and applied chemistry, both in a state of almost explosive expansion, are inextricably interwoven. Such a task could be undertaken successfully only by a writer of the exceptional calibre of the late Dr. Sherwood Taylor, in whom a scholarly outlook, a facility of expression, and a profound knowledge of the historical, theoretical and industrial aspects of chemistry were so happily blended.

Until the opening of the eighteenth century there was little connexion between chemical theory and the application of chemical knowledge; but from the middle of that century onwards the liaison between these two aspects of chemistry has grown ever closer. That is why the author found himself compelled, as the work progressed, to devote an increasing attention to the history of chemical theory.

The character of a book of this kind is perhaps determined as much by the arrangement of the material as by selection and emphasis. In the present instance, a short introductory survey of chemical industry precedes the two main parts of the book, which are concerned respectively with the pre-scientific and the scientific chemical industries. The eleven chapters of Part 1 are devoted to a consideration of important materials and processes, including metallurgy, ceramics, glass, combustibles, dyeing, and pharmacy. The thirteen chapters of Part 2 trace the concomitant progress of theoretical and applied chemistry, some of the main heads being scientific chemical industry, 1788–1860, the rise of theoretical organic chemistry, industrial organic chemistry, biochemistry, the discovery of the chemical elements, the road to nuclear power, the arrangement of molecules, electrochemical industries, the conditions of chemical reactions, and industrial gas-reactions.

The book is thus in effect a compact encyclopædia of the subject, written, however, in a lucidly flowing and attractive manner. It will open many new windows to readers having a thorough fundamental knowledge of chemistry; while the specialist may use it as a handy *vade mecum* from which, by virtue of a comprehensive index and a classified list of more than two hundred works of reference, he may gain more detailed information upon any matter of a historical, theoretical, or industrial nature in which he is particularly interested.

A high standard of accuracy is maintained throughout, and the matter is well up to date; but a few of the many points which naturally invite critical comment in a work of this wide scope may be mentioned. Although the author justifiably emphasizes principles rather than men in this treatment, he might well have given some credit to Glauber as an outstanding pioneer of applied chemistry. *Inter alia*, Glauber obtained coal-tar distillates as early as 1648, well in advance of Becher and Searle's "patent for making pitch and tar from coal in furnaces as early as 1681". It is somewhat surprising also to find no mention of John Clayton and his remarkable experiments (of which detailed accounts exist) with coal gas about the year 1687, although it is stated that "several persons seem to have experimented with coal gas during the [seventeenth] century".

Turning to a very different subject, the drawings on p. 222 purporting to be illustrations of crystals were described in my hearing many years ago by an irate stereochemist as "recurrent bow-windowed monstrosities". Moreover, it may be pointed out that "the sodium ammonium salt of racemic acid", which they are described as representing, forms monoclinic crystals quite distinct from the hemihedral rhombic crystals of the enantiomorphous sodium ammonium tartrates.

The profuse illustrations range from beautifully reproduced engravings after Agricola, Ercker, Biringuccio, Braunschweig, and still earlier sources, to the *dernier cri* represented by the frontispiece of the Windscale plutonium-producing factory. The type, paper, and format are excellent, and all concerned are to be congratulated on producing this attractive and valuable volume at so moderate a price.

John Read

NEUROPHYSIOLOGY AND THE INTRACELLULAR TECHNIQUE

The Physiology of Nerve Cells

By Prof. John Carew Eccles. Pp. xi+270. (Baltimore, Md.: The Johns Hopkins Press, 1957.) 5.75 dollars.

THIS book, based on the Herter Lectures delivered at the Johns Hopkins University, presents the latest development of the fundamental work by Prof. J. C. Eccles and his colleagues at Canberra on the properties of motoneurones as revealed by the intracellular technique of electrical recording. His earlier book, "The Neurophysiological Basis of Mind" (Oxford University Press, 1953), was written for a broad circle of readers. The new book is something of a supplement for neurophysiologists, a thorough exploration of the properties of the membrane of the motoneurone cell body in terms of 'inside' records. The four leading chapters are devoted to this task, the two remaining ones to a discussion of recent work and current ideas in neurophysiology.

The motoneurone cell body, some 70μ across, is penetrated by the tip of a glass capillary 0·5μ in diameter and filled with an electrolyte. In these large cells, situated in the ventral horn of the spinal cord, the wound is reasonably well sealed by the cell membrane, which closes up around the capillary so that reflex excitation and inhibition can be studied in terms of potential changes across the cell body. Some excitatory changes, especially long-lasting ones, are presynaptic and are thus not accessible to this technique, whereas others are determined by events in the cell processes or dendrites and only indirectly reflected in the cell body. Intracellular recording is therefore a technique for studying the 'effector' end in the chain of events, rather than all aspects of central nervous excitation. However, bearing this limitation in mind it has proved a fascinating tool. This approach originated with the Canberra group, and they have followed it up with outstanding skill.

Their most important generalization, since confirmed both for motoneurones and many other cells, still remains the discovery that monosynaptic reflex excitation depolarizes the cell along a characteristic curve, whereas inhibition drives the membrane back towards its equilibrium potential or even hyperpolarizes it. Theoretically, inhibition could also be obtained by excessive depolarization, and this case has been described elsewhere with cerebellar Purkinje cells, but apparently the characteristic responses found by Eccles and his colleagues are common for many types of nerve cells.

The book opens with a thorough account of the electrical properties of the cell membrane, as measured by themselves and others, and then proceeds to a presentation and discussion of the results obtained with double-barrelled microelectrodes. One barrel is used for changing the level of membrane potential by electrophoretic injection of anions or cations, while the other records the membrane potential and the effects of reflex excitation and inhibition. These difficult and skilfully conducted experiments are also hard to interpret in physicochemical terms, but nevertheless represent an approach to the problem that had to be carefully explored. They gave very valuable information on the generation of an impulse or spike in relation to level of membrane potential. Both excitation and inhibition will be found analysed in the book from these points of view. The fundamental line taken is that excitatory or inhibitory synaptic mediators or transmittor substances initiate the flow of ions, culminating in the excitatory or inhibitory changes of membrane potential studied. The rhythmic discharge of spikes is found to emanate from the region around the excitor axon hillock of the motoneurone, which seems to be specialized for the emission of signals down the axon.

The experimental work presented in this book has required not only skill but also patience and industry far beyond the ordinary. It is a pioneer effort rewarded by real insight into the electrical properties of nerve cell bodies and it has stimulated much research in many other centres throughout the world. Prof. Eccles does not shun discussion, so that the well-informed student of the central nervous system will find much more in the book than the presentation of a new line of approach to the physiology of nerve cells.

RAGNAR GRANIT

THERMODYNAMICS AND THE STRUCTURE OF MATTER

Thermodynamics and Statistical Mechanics

By A. H. Wilson. Pp. xv+495. (Cambridge: At the University Press, 1957.) 50s. net.

THERMODYNAMICS and statistical mechanics are commonly treated as separate subjects. They are, however, so closely connected that there is great advantage in treating them in a single book, as is done here. Six of the fourteen chapters are devoted to development of the fundamental theory, and the other eight to various applications.

In the first three chapters thermodynamics is developed in the classical manner. Now thermodynamics is a subject that is much easier to apply than to develop. Its historical development, which has happened in an illogical order, has added to the difficulties. Accounts of the first principles of thermodynamics are therefore often confused, and contain concealed assumptions or even circular arguments. Dr. A. H. Wilson has here given a clear account of the classical theory with all the assumptions precisely stated. But the classical development of thermodynamics, however well described, is not completely logically satisfying; in the fourth chapter, therefore, Dr. Wilson describes Carathéodory's axiomatic approach. Readers may choose, therefore, between the more logical approach of Carathéodory, and the less abstract one of the classical method; but there would be advantage in reading both accounts.

Chapter 5 discusses the foundations of statistical mechanics. As with thermodynamics, this is the most difficult part of the subject; application to a particular problem is simple by comparison. There are several possible methods of approach. Dr. Wilson starts by considering quantal systems; his fundamental assumption is that the value of any dynamical variable of a macroscopic system is obtained by taking the average of the variable over all the possible stationary states of the system. The relations of temperature, entropy, etc., to the energy-levels of the system are then developed. Use is made of Stirling's theorem, but Dr. Wilson is careful to point out the problems and difficulties involved in this.

Reference is then made to the Darwin–Fowler method of avoiding the use of Stirling's theorem and to the fundamentally different approach of Gibbs. Classical statistical mechanics is then derived as a limiting case of quantum statistical mechanics.

Chapter 6 gives applications of the formulæ previously obtained to problems of specific heat, and to systems obeying the Fermi–Dirac or Einstein–Bose statistics.

In Chapter 7 there is a return to fundamentals with an excellent account of the third law of thermodynamics; the nature of the underlying assumptions and of the experimental evidence is carefully stated.

The remaining seven chapters are devoted to applications of the theory. The possible applications are so many that only a selection can be made, and no doubt some readers will be disappointed that their particular interest is not dealt with. However, the majority will consider that Dr. Wilson has made a reasonable choice. He has described some of the subjects of a wide general interest to physicists and physical chemists, such as the theory of imperfect gases, vapour pressures, magnetism, chemical equilibrium, solutions, and electrolytes; and has also discussed some of the more recent problems, which are not discussed in the older books on statistical mechanics. Examples of these are properties of liquid helium, superconductivity, antiferromagnetism, ferroelectricity, rubber, and recent work on the order–disorder problem.

This is an excellent book; but though self-contained, it is not a book for the beginner, who would be well advised to start with one of the more elementary treatises on the subject. In the words of the author, it treats elementary matters from an advanced point of view and is suitable, therefore, for the student who has a basic knowledge of the subject and is anxious to put it on a sound logical foundation. Those engaged in research in one of the specialized topics dealt with will also be glad to consult it.

A. F. DEVONSHIRE

CHEMISTRY OF CO-ORDINATION COMPOUNDS

The Chemistry of the Coordination Compounds
Edited by John C. Bailar, Jr. (American Chemical Society Monograph Series, No. 131.) Pp. x+834. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1956.) 148*s*. net.

In recent years interest in the theory of co-ordination and co-ordination compounds has developed to a very marked degree, resulting in increasing application to many types of chemical work. Even to those not intimately acquainted with the subject, the use of organic precipitants for metallic ions will surely be familiar. This, however, represents but one small fraction of the application of co-ordinating agents. It could be claimed that, in some measure, the Werner theory of co-ordination published about sixty years ago is the guiding principle of our modern theories of acidity, basicity, hydrolysis, etc. To-day, applications of co-ordination theory are found in the use of co-ordinating agents for the extraction of metals from their ores, in electroplating, in catalysis of reactions, in water treatment and in the study of dyes and pigments. Undoubtedly very many other uses of these compounds await further investigation. The subject, therefore, has both theoretical and practical interest to the chemist in general, whether inorganic, physical or organic, but the lack of an authoritative source book has been an obvious disadvantage.

The editor of the present volume has clearly recognized this need, and, wisely deciding that the task was too great for one man, has produced a most comprehensive work to which twenty-four authors have contributed. The volume is published as one of the American Chemical Society's Series of Chemical Monographs. In the first section of the book the editor and Dr. D. H. Busch give a general survey of co-ordination compounds, the excellent documentation and style of which set the standard for the remainder of the volume. Three very interesting sections follow. In the first of these the historical development of the co-ordination theory is covered, and the following two embrace modern developments, with emphasis on the influence of the electrostatic theory and electron pair bond on the structure of co-ordination compounds. Other topics covered include chelation, and the theory of heterocyclic ring formation involving metal ions, with a separate section on large rings, the stereochemistry of co-ordination numbers 4, 6 and less common numbers, isomerization of co-ordination compounds, the stabilization of valency states by co-ordination, theories of acids and bases, amphoteric compounds as applied to complex substances and olated compounds, that is, complexes in which the metal atoms are linked through bridging hydroxyl groups. Special features include a study of the isopoly- and heteropoly-acids, co-ordination compounds of metal ions with olefins, the metal carbonyls and nitrosyls and organic molecular compounds.

Perhaps the section which illustrates most clearly the extent of the subject, and the comprehensive nature of this volume, is that describing the physical methods employed for the investigation of co-ordination compounds. To say that these are numerous is an understatement: they include X-ray and electron diffraction, tracer techniques, dipole moments, magnetic measurements and dialysis and electrolytic transference, apart from those which are more familiar. In a more applied sense the importance of co-ordinating agents is seen in those sections which survey their uses in analytical chemistry, water softening, electrodeposition and the formation of dyes and pigments. The literature associated with this subject is very large, and the authors have therefore restricted themselves to lists of references which have been critically selected on the basis of their importance and significance. Despite this, however, the number of references is more than five thousand, many of which are very significant for further reading on the subject-matter.

This is an excellent work and contains all the salient aspects of co-ordination chemistry. The emphasis on modern developments is especially valuable. Although the subject has been covered very extensively, a claim might be made for the inclusion of a section on the methods of preparing complex ions, in view of current interest. This book will undoubtedly prove of very great value to chemists and workers in allied fields and can be strongly recommended.

R. J. MAGEE

THE DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH

REPORT FOR 1955–56

THE annual report of the Department of Scientific and Industrial Research for the year 1955–56* includes the report of the Committee of the Privy Council for the year ended September 30, 1956, over Lord Home's signature, and the forty-first, and last, report of the Advisory Council, signed by Sir Harry Jephcott, which includes the customary summary of work carried out by the various research stations and boards and research associations. Besides the summary of the Department's expenditure for the year ended March 31, 1956, there are appended a copy of the Department of Scientific and Industrial Research Act, 1956, under which the present Advisory Council is replaced by an Executive Council, lists of assessors to the Advisory Council, of the various committees of the Advisory Council and their membership, of the research boards and establishments of the Department, of grants for special researches in progress or authorized during the year, of students awarded maintenance allowances for postgraduate training in research and a 49-page list of publications issued during the year.

The gross expenditure of £7,350,738 compares with £6,685,400 in the previous year and is reduced to £6,428,693 by various receipts (£407,222 being from the National Physical Laboratory) for work done for government departments or for industry, the net increase on 1954–55 being £530,677. The Department's net expenditure for 1956–57 has been reduced by about £150,000 as part of the Government's economy campaign, and although the effect of this reduction will be to slow down rather than stop the Department's programme of planned expansion and development, it is deplored by the Advisory Council. Moreover, two building projects—an experimental road system, designed as the first part of a new Road Research Laboratory, and a new chemistry building at the Building Research Station—on which work was to have started in 1956–57 have been deferred, and the Advisory Council urges very strongly the importance of an early resumption in full of the Department's building plans. On October 1, 1956, the Department employed 4,655 staff of all grades (including 200 part-time), compared with 4,379 (190 part-time) in the previous year, and as a result of this increase the deficiencies which had accumulated during the two preceding years have largely been overtaken. Annual grants to research associations totalled £1,423,775 (compared with £1,335,125 in 1954–55), grants for special researches amounting to £373,028 (£315,425 in 1954–55). Grants to students amounted to £319,919, a decrease of £3,103, the number of students in training in 1955 being 1,012, and in 1956, 1,006, and of these, 379 in 1955 and 404 in 1956 were new. Of eight senior research awards in 1955 and seven in 1956, five in 1955 and four in 1956 were new, and 15 new grants for special researches in 1954 and 46 in 1955 brought the total of such grants to 53 and 99, respectively, compared with 58 in 1953 and 64 in 1954. Of the grants for special researches, 33 in 1955 and 54 in 1956 were in physics; for chemistry, the figures were 9 and 14; for biology, 4 and 7; for engineering, 4 and 5; for mathematics and astronomy, 1 and 7; and for geology and mineralogy, 1 and 8. In 1955 chemistry claimed 399, and in 1956 372, of the students receiving grants; in physics the corresponding figures were 262 and 256; in biology, 107 and 108; in mathematics and astronomy, 86 and 96; in engineering, 91 and 42; in geology and mineralogy, 42 and 43; and in chemical engineering and metallurgy, 23 and 58.

Expenditure on the National Physical Laboratory of £946,890 gross or £542,668 net was slightly less than in 1954–55 (£556,435), and there were also decreases in the expenditure on food investigation (from £373,208 to £358,528 net), radio research (from £107,298 to £104,119 net) and forest products research (£116,487 to £116,161); but expenditure on the other branches of the Department's activities increased, the largest increase being in the expenditure on mechanical engineering research (from £315,561 to £436,006). Net expenditure under the other major headings in 1955–56 was as follows, the increase over 1954–55 being given in brackets: building research, £492,701 (£39,652); road research, £388,436 (£44,920); fuel research, £288,260 (£17,841); Geological Survey and Museum, £268,046 (£44,636); Chemical Research Laboratory, £139,226 (£2,876); hydraulics research, £84,046 (£7,877); water pollution research, £76,482 (£2,161); pest infestation, £72,284 (£4,139); fire research, £31,781 (£9,348); headquarters, administration, etc., £272,581 (£24,636), and headquarters, overseas liaison, etc., £76,235 (£5,797).

The contribution to the European Organization for Nuclear Research also increased from £359,787 to £519,996, and while only some £40,000 out of the expenditure of £315,425 net on grants for special researches authorized in the year ended September 30, 1956, was for nuclear research, grants totalling more than £800,000 had been authorized prior to October 1, 1955, for nuclear physics research still in progress, as well as more than £40,000 for equipment.

Those research stations with the work of which the Advisory Council's report is this year specially concerned are the Road Research Laboratory, the Water Pollution Research Laboratory and the Chemical Research Laboratory, all of which were visited by the Advisory Council. The Advisory Council was particularly impressed with this, its first, visit to the new Water Pollution Research Laboratory at Stevenage, and was satisfied that the work is well planned to achieve results of practical value and that co-operation with 'user' interests is outstandingly good. In particular, the Advisory Council believes that in the survey of the conditions in the Thames, undertaken in co-operation with the Port of London Authority, the work of the Laboratory has pointed the way to a proper understanding, of the greatest economic value, of the effects of the manifold sources of trouble in the river, and of their complicated interactions and seasonal variations. The investigations have made it possible to devise reliable methods of forecasting the effects of a new source of pollution or of a new remedial method, and by so doing have provided a quantitative basis for assessing the best and most economical means for dealing with a problem vital to the health and work of Londoners. Other work of the Laboratory has been concerned with the tolerance of different species of British freshwater fish to low concentrations of dissolved oxygen over the range of temperatures to be expected in British rivers.

---

* Department of Scientific and Industrial Research. Report for the year 1955–56. Pp. 314 (Cmnd. 213.) (London: H.M. Stationery Office, 1957.) 9s. 6d net.

In the two main sections of the Road Research Laboratory, a little less than two-thirds of the resources are devoted to problems of road construction and a little more than one-third to safety and traffic. The Laboratory's investigations on the possible economic returns from building new roads appear to be of particular interest at present, and it is expected that the new road construction programme will offer greater opportunities for use of a trial method of assessment which has been worked out. The Advisory Council was impressed with the contribution which the Laboratory's work is making to improving the quality and lowering the cost of road construction and pointing the ways to a smoother flow of road traffic and the achievement of greater safety. As particular examples may be mentioned the Laboratory's study of the effectiveness of the various ways of indicating a turn, including flashing indicators and semaphore arms, now in use on vehicles; of the bearing of street lighting on accidents, and on the development of standards of minimum resistance to skidding for different types of roads; its study of the stabilization of soils with a high clay content, of soil compaction, and of testing techniques for rapidly assessing the quality and thickness of the various layers forming a road and for determining the load-spreading characteristics of the road structure.

The Advisory Council was much impressed with the scientific quality of the work of the Chemical Research Laboratory. The Council emphasizes that the Laboratory is intended to undertake chemical research on selected problems of national interest, and on investigations on lines for which no provision exists in the universities or in industrial laboratories. The emphasis on the importance of careful selection of subjects may be of special significance in view of the change in the organization of the Department under the new Act. In further work on the separation of individual rare earths by ion-exchange methods, the Laboratory has found that improved separations are obtained if the rare earths are diluted with ammonium ions so that they occupy a longer length of the ion-exchange column. Two new instruments have been developed for applying the technique of zone-melting to the separation and precipitation of organic compounds, a new technique has been developed for fractionating high polymers and encouraging progress made in the development of paper-strip chromatography as a micro-method for the determination of molecular-weight distributions of polymers.

An investigation by the Building Research Station has shown that savings in water consumption amounting to more than a million gallons a year with a decrease in solid fuel consumption of more than 50 tons could be achieved in a large office building with a staff of more than a thousand by substituting spray taps (supplying blended hot and cold water) for the normal pillar taps used for washing. Other work of the Station has indicated the possibility of reducing the cost of a flat in a block of six stories or more as much as £450 a flat by combining the economic features of different designs, and research in co-operation with the Midland Regional Board for Industry is endeavouring to provide authoritative data on the most suitable and economic forms of factory design and construction. An investigation into casualties caused by the ignition of clothing, while not yet complete, has indicated the need for increased emphasis on the design of clothing, on the use of fire-guards and on increased care for the young and old, while the textile industry continues its researches on flame-retardant treatments.

In food investigations the potential use of antibiotics in the preservation of fresh foods is being studied experimentally, and the small unit of the Low Temperature Research Station at Cambridge has resumed its studies of the use of ionizing radiations to extend the storage life of selected foodstuffs. For this purpose it has been strengthened by staff seconded from the British Food Manufacturing Industries Research Association and from industry. Other investigations are concerned with the serious wastage in the meat industry from the concealed loss of offal and tissues of the carcass when an animal is being taken to an abattoir and rested before slaughter, the reasons for the marked decline in consumption of smoked fish and the development of improved processes for smoking. Use of nonyl alcohol vapour has been found to provide a simple, effective and cheaper method of suppressing the sprouting of potatoes on a pilot-scale up to 15 tons; and further work on the application of refrigeration and the use of carbon dioxide in the transport of soft fruits has made it possible to specify the conditions required for successful pre-cooking of soft fruits and transport from farm to market.

The Forest Products Research Laboratory is devoting increasing attention to the study of home-grown softwoods, and besides developing simpler and more effective methods of bending for industrial use, has attempted to devise a method of impregnating test samples with low concentrations of creosote while ensuring its uniform distribution. In co-operation with the Atomic Energy Research Establishment, the treatment of infested timber with gamma-rays has received much attention. The Fuel Research Station intensified its efforts towards the efficient utilization of the more plentiful coals, including those of small size and comparatively low quality, and the Station also obtained a correlation between mortality and the observed atmospheric pollution in the different districts of London.

A generous financial grant by the Nuffield Foundation for an airborne magnetic survey to allow assessment of the potentialities of the method and study of alternative techniques permitted a survey of about 11,000 sq. miles in the Midlands, and concurrently magnetic measurements were made at about twenty-five ground stations distributed over the whole of Great Britain. A survey of Norfolk showed that only about 5 per cent of the available ground-water resources are being used; a similar survey is being made in south-east Lincolnshire.

The staff of the Mechanical Engineering Research Laboratory increased by 14 per cent during the year, but the general balance of fundamental and applied research was little changed. The special equipment for basic research on the principles underlying the design of hydraulic machinery has been completed with the erection of a closed circuit for cavitation research on water-turbines. Much attention is being given to fundamental studies of wear, and a fundamental investigation of the causes of varying adhesion between wheel and rail is being carried out for the British Transport Commission. Two very accurate electric dynamometers have been developed for research on power transmissions, and the Heat Division is attempting to provide more accurate basic design data for conventional and novel types of heat exchanger.

The work of the National Physical Laboratory has recently been reviewed in these columns and no more need be added here than that the Control Mechanisms and Electronics Division is sponsoring the development of auxiliary machinery which would permit the cost of certain clerical tasks to be cut by more than 50 per cent by using types of scientific computer now on the market, and that work in the Ship Division has shown that on the same power output a well painted and a badly painted ship may differ by as much as half a knot in speed. Work on grain storage has shown that quite damp grain, such as may be harvested by combine in a wet season in Britain, can be stored for several months in air-tight metal bins without detriment to use for feeding to stock. The new laboratories at the Radio Research Station, where studies on the propagation of radio waves over a very wide band of frequencies absorbed the bulk of the effort in radio communications research, came into use in June 1956. In radio-navigational aids the effort has now been diverted to much lower frequencies which show promise of being suitable for use at longer distances, while in work on semiconductors an appreciation has been obtained of the dependence on frequency of the noise per unit bandwidth developed in monocrystalline filaments of germanium carrying current, and in back-biased, point-contact and junction diodes.

During the year 1955–56, grants were offered to two new research organizations, bringing the total of grant-aided bodies to thirty-nine research associations, seven research councils or committees not yet of research association status, and three other institutions the activities of which are of special interest to industry. A block grant of £3,000 a year, conditional on £6,000 of grant-earning income from the industry with up to an additional £4,000 on a cent-per-cent basis, was offered to the Heating and Ventilating Research Council for the period January 1, 1956–December 31, 1958, to provide a co-operative research organization for an industry with an estimated annual turnover of £35 million and employing some 12,000–13,000 operatives. A grant to the National Institute of Industrial Psychology on the same terms as those governing grants to research associations will make possible sustained studies of general interest, and the grant terms of the Commonwealth Mycological Institute have been modified for the final two years of the current grant period. A special grant was offered to the British Coke Research Association for the erection of a full-scale coke-oven plant, the first in Britain to be available for research.

New terms of grant were offered to eight research associations and research councils during the year. The Printing, Packaging and Allied Trades Research Association will receive for the period April 1, 1956–March 31, 1961, a block grant of £27,000 conditional on £67,500 coming from industry, with up to a further £18,000 on a cent-per-cent basis. A main research project has been an investigation into what constitutes a good print, so that a method of comparison can be evolved. A new damping solution which will minimize the printing of non-image areas without leading to other troubles, and a treatment for preventing damping rollers from rotting have been introduced for lithographers; further progress has been made with the development of a contact screen capable of giving improved tone reproduction in lithography, development work has continued on tests for assessing wear-resistance of book-binding materials, and accurate information is being accumulated on how packages behave in transit as a basis for improved design of containers.

The past year's work of the British Baking Industries Research Association, which, for the period July 1, 1956–June 30, 1957, will receive a block grant of £11,000, conditional on £20,000 coming from industry, with up to a further £8,000 on a cent-per-cent basis, reflects the influence of technological advances generally on a traditional industry. New techniques in mixing indicate changes in baking methods which may offer more economical production and products of improved quality, while deep freezing of bread, flour confectionery, doughs and batters also offers promising possibilities. Long-term experiments now completed indicate that no loss of vitamin B_1 occurs during the fermentation of bread dough; but in baking, 17·3–23·3 per cent of this vitamin is lost and, depending on the thickness of the slice of bread, a further 13·4–31·0 per cent is destroyed during toasting. One of the most important investigations of the British Jute Trade Research Association, the block grant of which has been increased to £16,000 a year for the period July 1, 1956–June 30, 1961, provided £27,000 is received from industry, with up to a further £10,000 on a cent-per-cent basis, is concerned with improving the quality of jute yarns as a result of changes in carding procedures. A special softening machine has been developed to provide different types of fireproof finishes on jute cloths using a process developed in the laboratories, and an investigation on minimizing fibre degradation under exposure to sea-water has been largely completed. Basic and fundamental research (about one-fifth of the total effort) has been devoted to elucidating the chemical structure of the jute fibre and the mechanism of chemical reactions which adversely affect fibre properties.

The Research Association of British Paint, Colour and Varnish Manufacturers will receive a block grant of £22,500 for the period July 1, 1956–June 30, 1961, conditional on £45,000 coming from industry and up to a further £12,000 on a cent-per-cent basis. Radioactive tracer techniques have proved of great value in studies of reaction mechanisms involved in processing drying oils and in the drying of films, while in work on epoxide resins infra-red spectroscopy has been used to follow the basic reactions during curing with amines and polyamides. Methods of assessing the particle-size, shape and distribution and total surface area of pigment powders are being made more effective and reliable, and the crystal structure of pigments has been further investigated; much has been learnt by direct observation of the position of pigment particles in paint films, singly or in clusters and at various depths. A study of spectrophotometric and potentiometric titration of chromate ions in acid solution has led to a method of determining chromates in pigments, and the effects of selected pigments have been closely examined in relation to the build-up of films and their breakdown. For the period July 1, 1956–June 30, 1961, the British Rayon Research Association will receive a block grant of £80,000 a year, conditional on £250,000 being received from industry, with an additional £50 for each £100 contributed by industry up to a maximum of £10,000. In fundamental research considerable progress has been made in elucidating the precise molecular arrangements in the crystalline forms of cellulose, particularly by using infra-red spectroscopy, while a study of the kinetics of the photochemical breakdown of cellulose in the presence of dyestuffs has established that the activated triplet state of the dye molecule is responsible for the breakdown. The Association has undertaken a programme of work on blended yarns, and finds that there are no outstanding difficulties in spinning, warping and weaving in producing cloths from blends of viscose with acetate rayon, nylon, 'Terylene', 'Orlon', 'Celon' and 'Acrilan'. Application of fluid-bed techniques in textile processing operations, such as drying, dyeing and finishing, appears to offer great potential savings.

For the period April 1, 1956–March 31, 1958, the British Scientific Instrument Research Association will receive a block grant of £40,000 per annum provided that £25,000 is received from industry, with up to a further £15,000 on a cent-per-cent basis. Progress is being made in an important investigation of ceramic elements which are sensitive to humidity, and an improved amplifier has been devised for the millivolt-level. A method of calculating the transmission characteristics of multi-layer interference filters has been developed. The main work of the British Electrical and Allied Industries Research Association, which for the period January 1, 1957–December 31, 1958, will receive a block grant of £100,000 a year, conditional on £200,000 coming from industry, continues to be concerned with the generation of electrical energy, its economical transmission and distribution, its most efficient utilization and the reliability of equipment, and about 15 per cent of the effort continues to be of long-term fundamental character. The hydrogen–oxygen fuel cell is now ready for industrial development, and new ground has been broken in the study of the interruption of circuits *in vacuo*. There appear to be promising applications to high- and low-power switchgear, contactors and rectifiers. The use of digital computers has permitted the application of more accurate mathematical methods of calculating short-circuit forces in transformers; laboratory work continued on basic problems of crop drying and the design of farm-dryers has been improved. A study of the relation between moisture content and discharge inception in impregnated paper insulation has established a strong correlation between these properties, while the study of ferro-electric materials is now directed to mixed sodium/potassium niobates. The Wool Industries Research Association, which for the period October 1, 1956–September 30, 1958, will receive a block grant of £40,000 a year, conditional on £110,000 coming from industry, with up to a further £30,000 on a cent-per-cent basis, is putting into production a dropper pinning machine, which eliminates much labour in setting up the warp stop motion on automatic looms. The Raper autoleveller drawing system, in the development of which the Association assisted, has proved most successful, offering a 10 per cent saving in labour as well as significant reduction in waste. Work on piece scouring has shown how economies in the use of hot water as well as in scouring-time can be obtained while maintaining or improving the quality of the product, and a more detailed study of fibres containing radioactive cystine showed no differentiation between the ortho- and para-keratins which have been postulated for the two halves of the fibre.

Of the work of the remaining research associations, only a few points can be mentioned here to illustrate further the many-sided bearing of the Department's work on the national life of Britain. The British Boot, Shoe and Allied Trades Research Association has done much practical work on the difficult problems of securing suitable adhesion between the uppers of shoes and newer synthetic solings, and promising and original work has been done at an experimental training centre to develop methods of selecting and training untrained labour for stitching operations in shoe factories. The British Ceramic Research Association has designed a satisfactory hood for the control of dust from the towing process and for dealing with the allied problem of hollow-ware fettling, as well as studying the effect of rate of drying on strains set up in clay bricks and blocks and the magnitude of the stresses that cause cracking. The British Coal Utilization Research Association has constructed special apparatus, consisting of a model fuel-bed burning beneath an electrostatic precipitator, for measuring the smoking tendency of coals and of manufactured smokeless fuels. The Cutler Research Council has developed a process for bending curved scissor blades that has been almost universally adopted by that section of the trade.

Fundamental data on the nutritive value of the proteins of flour, obtained by the Research Association of British Flour-Millers, indicate that the potential value of wheat protein is only fully mobilized in the presence of relatively small amounts of other proteins which are good sources of lysine. When these conditions are realized, the protein of wheat assists notably in maintaining a high biological value for the mixed proteins in the diet; and, so far as the protein content is concerned, the rate of extraction of the flour then becomes unimportant. The British Food Manufacturing Industries Research Association has extended its study of the increase in 'mould count' of soft fruits during transport and its retardation under improved conditions of transport, and the Fruit and Vegetable Canning and Quick Freezing Research Association is again investigating the chemical and physical changes during the ripening of green peas for canning and freezing. By the use of trypsin digestion in measuring the average molecular weight of fractions of gelatin by the technique of light scattering, the British Gelatine and Glue Research Association has removed the principal uncertainty in this method, the gelatin being degraded in a few minutes to an extent which permits the direct measurement of scatter due to impurities. A major project of the British Glass Industry Research Association is to reach some understanding of the mechanical strength of glass; while the fundamental work of the British Hydromechanics Research Association on the flow of liquid–solid mixtures in pipes has been extended from the behaviour of relatively large particles—of particular interest in connexion with coal transport—to smaller sizes of material. The new continuous casting plant of the British Iron and Steel Research Association promises to give outputs of steel considerably higher than the present 7 tons an hour. The new method of flame-proofing nylon net devised by the Lace Research Association is now being used on almost all nylon net placed on the market by the industry. The British Launderers' Research Association has found that 'Polythene' is suitable only for low-temperature washing, but that some 'Terylene' garments will stand processing of the type suitable for white cotton. A dominant feature of the work of the British Leather Manufacturers' Research Association has been the study of methods of producing leathers with specific properties, such as hard wear, water-proofness and flexibility. Investigations by the Motor Industry Research Association point to the possibility of virtually eliminating brake squeal at small cost, and the Association has also sponsored a study of the mechanism of oil consumption by the engine piston and rings. The non-destructive thickness gauge for metallic coatings invented in the British Non-Ferrous Metals Research Association's laboratories has now been developed to measure the thickness of duplex coatings, particularly nickel and copper coatings on steel and on zinc die-castings, while progress is reported in the production of thick uncracked chromium deposits, using conventional plating plant and procedure. Oil-less water-based cutting fluids containing non-proprietary corrosion inhibitors developed by the Production Engineering Research Association have offered important savings to manufacturers of such fluids, and work of the Research Association of British Rubber Manufacturers on the prevention of deterioration due to traces of copper, manganese and iron using sequestering agents has added greatly to our knowledge of these oxidation processes and how these trace metals and sequestering agents work.

SCIENCE IN SCHOOLS

A SESSION of Section X (Corresponding Societies) of the British Association for the Advancement of Science was held on September 10 in the Great Lecture Theatre of the Science Buildings of University College, Dublin. The audience, which was large, included Prof. P. M. S. Blackett, president of the Association, and Mrs. Blackett; Dr. Henry St. John Atkins, president of University College, Cork; The Rev. Prof. J. McConnell, of Maynooth; Dr. A. C. Williams, senior chief inspector of the Ministry of Education of Northern Ireland; Mr. P. McGeown, inspector of the Department of Education in Eire; Prof. J. Doyle, Prof. T. Murphy and Prof. F. Hackett, of University College, Dublin. Prof. D. A. Webb, of Trinity College, Dublin, president of Section X, was in the chair.

The Rev. Dr. M. T. Casey, lecturer in general science at Maynooth College and senior science master at Newbridge, opened the session with an address on "Science in Our Irish Schools". He said that only 60 per cent of the boys and less than 50 per cent of girls take an academic science subject at Leaving Certificate level. In girls' schools generally—with some very notable exceptions—academic science is much neglected. Very few take physics or chemistry. Some take botany, but the majority select physiology and hygiene as a kind of 'soft option'. In the absence of physics and chemistry, this subject loses a great deal of its value. All this is to be deplored, especially as there is no valid reason why girls should not reach a degree of proficiency in science comparable to that attained by boys.

The great difference between the attitude of Irish and British schools to science is to be explained by the difference in industrial conditions. Britain, heavily industrialized, is only with difficulty able to meet the demand for scientists, whereas in Ireland industry is not so insistent and the supply usually exceeds the demand. This has its repercussions in Irish schools, where the arts subjects tend to dominate the curriculum. Now, modern science, apart from its being a major force in world affairs, has a very definite and unique cultural value, for it discovers in an ever-increasing measure the beauty of form and function that abounds in Nature which itself is the handiwork of the Creator. If the study of the arts—the mere artefacts of man—is cultural, how much more so the study of Nature itself. Science has a very definite and irrefutable claim to be taught even for its own sake and in all schools, for it forms an essential part of a liberal education. A person who knows nothing about science must be regarded as only partially educated. In Ireland specialization at school level is not envisaged, hence it follows that the exclusive study of physics and chemistry as the only science subjects at this level is unsound in principle, since it narrows down the outlook of the young mind. Biology must form an integral part of every school science course. To neglect biology is to neglect at least one half of natural phenomena. In Ireland, where the basic industry is agriculture, the teaching of biology becomes a national necessity.

In Ireland there is a scarcity of science teachers owing to the absorption of science graduates by industry. This could be remedied by asking the teaching priests, nuns and brothers to take up science teaching in greater numbers.

The first of the juvenile lectures was given by Mr. John D. Gallivan, of the sixth form at Newbridge College. He read a very interesting paper, illustrated by lantern slides, on "The Reverend Dr. Callan of Maynooth, pioneer of electrical research". Callan was born in Co. Louth about 1799 and spent the greater part of his life in St. Patrick's College, Maynooth, where he held the chair of natural philosophy from 1826 until his death early in 1864. Attracted by the researches of Faraday and Sturgeon, he built a giant horse-shoe magnet, some 7 ft. high and weighing 210 lb. When supplied with current from his battery, this magnet could lift two hundred times its own weight. Before 1836, Callan had investigated the principle of the electric motor and had built three. In the earlier forms, he employed a wheel having horizontal soft-iron bars attached to its rim. This was made to rotate by an intermittently energized electromagnet placed under it, the interruptions of current being made by the rotating wheel. A later model using forty electromagnets was able "to

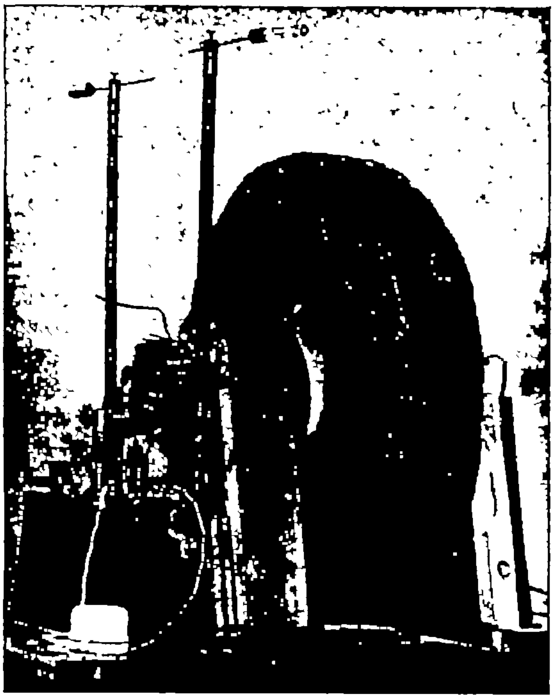

Fig. 1. Callan's medium-sized induction coil, now in the College Museum, Maynooth

propel at eight miles per hour, a thirteen hundred-weight carriage". Callan also experimented with various types of primary cell and eventually arrived at one which was manufactured commercially by E. M. Clarke, of The Strand, London, and called the "Maynooth Battery". The positive plate was a cast-iron container, holding a porous pot with the zinc plate enclosed.

Callan's most important invention was the induction coil. When repeating some of Faraday's experiments on electromagnetic induction, Callan found that the shorter the interval at break, the higher the voltage of the induced current. From the escapement mechanism of an old clock, he constructed an interrupter which gave several thousand interruptions per minute. Using this apparatus coupled to his horse-shoe magnet on which he wound a secondary coil over the primary, he found that the machine would give prodigious shocks. He sent the whole apparatus to Sturgeon, who demonstrated it at the London Exhibition of 1837, where it attracted much attention. Callan now constructed his 'medium-sized' coil. This had a bundle of soft iron rods as core on which he wound the primary coil. Over this he wound a secondary coil of very fine wire very carefully insulated. The interrupter was of the trembler type devised by his contemporary, Prof. McGaulay, of Dublin. This apparatus gave very considerable sparks. Callan still continued and made his giant induction coil, which was built on the same principle as the medium one. The core is 42 in. long and the primary coil is made from copper wire, ¼ in. in diameter, insulated with thread and wound in three layers. The whole is enclosed in an insulating paste made from wax and gutta percha. The secondary consists of three coils each containing about ten miles of very fine iron wire all carefully insulated with his paste. Callan had a large condenser across the interrupter, and using three cells of his Maynooth battery to feed the primary coil, he got sparks 16 in. long from the secondary terminals.

For some time Callan's claim to the invention of the induction coil was in dispute, but it has long since been vindicated beyond all controversy. The principal evidence is to be found in Callan's own papers published in Sturgeon's *Annals of Electricity* (1, 493; September 11, 1837), where we have the first known reference to the modern induction coil, and also in the *Philosophical Magazine* (1836). Noad's "Treatise on Electricity" (1857) and Prof. J. A. Fleming's "The Alternate Current Transformer" also pay tribute to Callan as the inventor of the induction coil. Furthermore, French writers no longer claim Ruhmkorff (who constructed his first coil in 1851, fourteen years after Callan's) as its inventor. Mr. Gallivan concluded his paper by paying a tribute to Prof. McLaughlin, vice-president of Maynooth, whose researches had rescued Callan from oblivion.

Miss Valerie B. Poynton, of Alexandra College, Dublin, read a very interesting account of a year's practical work in the realm of marine zoology, entitled "Round Dublin in the Steps of a Marine Biologist". The undertaking of the actual work was inspired by the book "Life of the Shore and Shallow Sea", in which Douglas Wilson urges the would-be naturalist to see the inhabitants of the sea-shore in their natural surroundings. Miss Poynton agreed that while the preserved specimen had undoubted reference value, it could never replace the living animal. "The graceful undulating movement of the planktonic worm *Tomopteris*, as it flashes through the water, provides an unforgettable sight; while the symmetry and beauty of the delicate comb-jellies and the geometric precision with which they move their cilia can never be visualized by those who have not

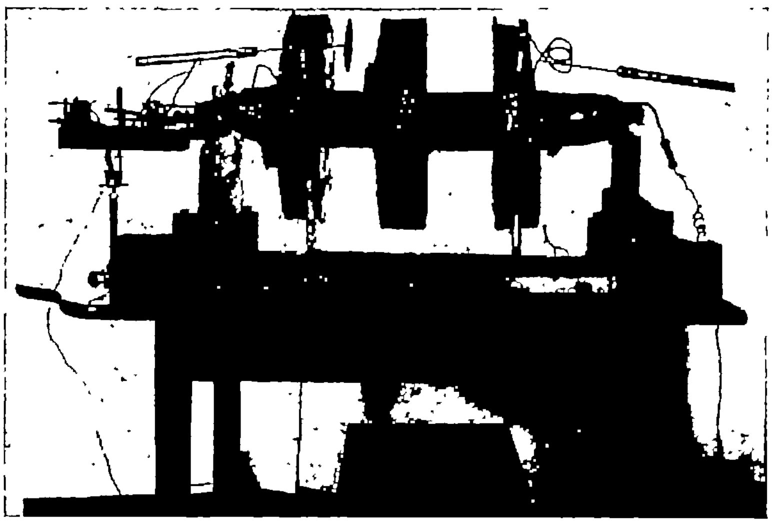

Fig. 2. Callan's 'giant' induction coil, now in the College Museum, Maynooth

had the good fortune to have seen those animals alive." Although the survey extended all around Dublin Bay from Malahide on the north side to Dalkey on the south, Dalkey Island itself formed the background of Miss Poynton's paper. The island has an area of 21 acres and is separated from the mainland by a narrow Sound. It is nine miles south of Dublin and owes its name to Danish invaders. 'Dalkey' comes from the Gaelic 'Deilginis', which means 'Thorn Island'. The area has granite for its underlying rock—it lies at the extreme tip of the Leinster granite chain—and Dalkey Sound may have been due to glaciation.

Methods of collecting and preserving material were described. Dredging was mentioned as the 'most exciting' method, since each new dredge held unlimited possibilities; there was always the chance that something new and long-sought might appear, while plankton-hauling could be described as most fascinating.

A short account was given of the environment of marine animals and of the hazards which they must overcome in order to survive and reproduce. Life in the rock pools differs from both life in the open sea and life under the boulders of the shore, so that the environment of the fauna in the immediate vicinity of Dalkey is quite complex. It is a series of environments rather than one well-defined habitat.

The commonest members of the fauna were discussed so vividly that the speaker seemed to communicate some of her enthusiasm to her audience. Her subjects ranged from the lowly sponges to the larger fishes and they were aptly illustrated by living specimens in aquaria on the bench. Very clearly, Miss Poynton's "year's work became something in the nature of a treasure hunt which was very well rewarded".

Mr. Jonathan R. Tinker, of the sixth form at Charterhouse, delivered a lively address on "Bird Reserves". He briefly discussed the various kinds of reserve, which ranged from small sanctuaries in private gardens to the great national reserves such as the Yellowstone National Park in the United States. As a result of the Wild Birds Protection Acts, special areas had been set aside in the wintering, feeding or nesting grounds of certain species. He classified these reserves as being fourfold in type. First, there are those which aim at the preservation of a particular species threatened with extinction, for example, the red-necked phalarope sanctuary in Co. Mayo, and Havergate Island in Suffolk which protects the unique avocet colony. Texel in Holland protects a large colony of spoonbills, and there is a large area set aside in Canada for the whooping crane. The second type of reserve protects a small number of species like the Humber Wild-fowl Refuge in Yorkshire with its large areas of mud-flats for the protection of wild geese. Within this type, too, are the islands off the Pembrokeshire coast. The third type comprises those large tracts known as national parks which are maintained for their plant and animal communities. Lastly, there are various city parks, such as Phoenix Park in Dublin and Regent's Park in London, where birds are treated as just another amenity to be enjoyed by visitors. In Regent's Park there are some extremely rare wild fowl, including the mandarin duck. An important study of the breeding habits of the tufted duck has been recently carried out in the London parks. These sanctuaries have been quite successful in increasing the stocks of rare birds, but many problems arise in this matter, as, for example, that of the nightly destruction of large numbers of eggs in the ternery at Dungeness in the early post-war years. This was eventually traced to hedgehogs, and wire netting solved the problem. In the larger reserves the aim is to preserve the community, and it has been found that even a slight interference with the natural habitat may have profound ecological repercussions. The question of access to bird sanctuaries is always a thorny one. Normally, ornithologists and the interested public should have access to the reserves provided their presence will not have any disturbing effects. If such effects are serious, then even the ornithologists should be excluded.

Mr. Tinker said that in shooting birds sportsmen were selfish, for the dead birds were no longer available to others. Bird-watchers, on the other hand, enjoyed themselves and left the birds to be enjoyed by others.

Miss Christabel Smyth, of Alexandra College, Dublin, read to the meeting an account of "A Geological Tour in the Neighbourhood of Dublin". The area covered by this study extends north and south from Dublin to Rathdrum in Co. Wicklow and east and west from the coast to Poolaphuca in the Blessington Lakes. It falls into two main divisions: (*a*) a highland area—the Leinster chain—and (*b*) a lowland area to the north of the Leinster chain including the extreme eastern limit of the central plain of Ireland.

The rocks of the region are nearly all sediments of the Lower Palæozoic period, while the igneous intrusion of granite is associated with the Caledonian movement in Ireland. The sedimentary rocks include the Cambrian Bray series, the Ordovician shales and schists lying to the east and west of the granite intrusion and aureole, and the Carboniferous limestone north of the Leinster chain. This stratum is rich in fossils, especially around Malahide. The igneous rocks of the Ordovician period include dykes and sills of andesite, lavas and ashes. The volcano which lay east of Lambay Island radiated out dykes which may be seen on Howth and on Bray. The Leinster chain is the longest granite intrusion in the British Isles.

It is noticeable that the relief has been influenced by two main factors, namely, the rock type and glaciation. The different rock types have caused the characteristic shapes of the mountains, as the typical conical appearance of the sugar loaf quartzites and the smoothly rounded profile of Djouce Mountain, which is a granite formation. Glaciation has left many of the usual features. The district of Glendalough contains a number of these, U-valleys being numerous, the Lugduff brook culminating in a hanging valley and Lough Nahanagan in the Glendasan valley being a well-formed corrie. Boulder clay has been deposited thickly in many places. Moraines in many of the valleys form quite prominent features and glacial lakes have also been formed, as in the case of the lakes at Glendalough and at Blessington. The lecture was illustrated by coloured slides.

These papers on such diverse subjects point to great possibilities. The enthusiasm of the young authors was infectious, and they were greeted with warm applause. The generous Press notices of the session should be of great help in the campaign for more science in the schools. MICHAEL T. CASEY

THE ABYSSAL CIRCULATION OF THE OCEAN

A SYMPOSIUM on "The Abyssal Circulation of the Ocean" was held at the General Assembly of the International Union of Geodesy and Geophysics in Toronto during September 5–6. So very little positive knowledge exists about the nature of the deep circulation that it is possible to maintain entirely different points of view. G. A. Riley (United States) reviewed the steady-state theory, proposed some thirty years ago by Merz, Defant and Wust. This view appears to be partially confirmed by F. C. Fuglister's (United States) recent re-survey in *Crawford* of two original profiles across the South Atlantic by *Meteor* in 1925–27. As Fuglister showed, there is little observable change in either the temperature or salinity of the deep waters in the northern South Atlantic over the thirty-year interval (in the Deep Water of both eastern and western troughs there is a decrease of temperature of less than 0·04° C. and an increase of salinity of less than 0·04 per mille, and in the Bottom Water of the western trough an increase of both temperature and salinity of about 0·02° C. and 0·02 per mille). On the other hand, L. V. Worthington (United States) maintains, on the basis of what appears to be a general decrease of concentration of dissolved oxygen in the deep waters of the Atlantic between 50° N. and 16° S. since about 1925, that the deep water of the North Atlantic (below 2,000-m. depth) is now isolated from the surface and is no longer being renewed during the winter by sinking water masses off Greenland as is generally supposed. L. H. N. Cooper (United Kingdom) presented evidence that corrosion products in reversing water bottles may absorb oxygen from sea-water at a serious rate, and that with a new set of bottles, erratic variations in concentration of deep-water oxygen may occur near a continental slope. Thus Cooper holds that judgment may need to be suspended on Worthington's conclusions, based as they are on oxygen data. Riley believes that the North Atlantic deep waters have never been wholly depleted of oxygen in the geological past, so that it is unlikely that at present there can be very large fluctuations in oxygen content. It is difficult to reconcile this view with the quite firm indication to the contrary shown by Worthington's data.

The new hydrographic surveys of the North Atlantic by *Discovery II* and *Atlantis* were made using the new Schleicher–Bradshaw salinity bridge instead of the traditional salinity titration determination method. Thus a new high degree of resolution in the functional relation between salinity and temperature (the *T–S* relation) has been disclosed. The reason for such a relationship has always been completely obscure; however, N. P. Fofonoff's (Canada) new studies of the effect of the non-linearities of the equation of state of sea-water on the vertical stability and mixing appear to indicate ways in which this hitherto mysterious relationship may be explained.

One hopes that the new interest in the ocean on the part of the geochemists will result in many helpful geochemical studies of the distribution of rather esoteric properties of sea-water which may shed light on the problem of the circulation. In fact, it was suggested that it might be a good idea to try to organize, under international auspices, a world geochemical expedition to explore the entire world-ocean, and to procure a special ship and other necessary equipment. W. C. Broecker and his collaborators (United States) presented recent measurements of carbon-14 made at the Lamont Geological Observatory from water samples at a number of positions in the North Atlantic Ocean, indicating a mean residence-time of 650 years for deep water in the North Atlantic and also a rather large lateral mixing sufficient to produce near-homogeneity of carbon-14 over the deep North Atlantic. F. Koczy (United States) estimated values of the vertical eddy diffusivity from measurements of the vertical distribution of radium over the deep ocean floor. The use and implications of the distributions of particle content as an indicator of water mass were described by N. G. Jerlov (Sweden), and of the ratio of oxygen-18 to oxygen-16 as an indicator of source of water by B. Benson (United States). A. C. Redfield (United States) described the relation of the phosphorus content of the world-ocean to its general circulation, and presented a chart of the distribution of phosphates at 2,000-m. depth over the world-ocean.

H. Mosby (Norway) and J. Eggvin (Norway) described conditions in the Norwegian Sea, and G. Dietrich (Germany) the occasional floods of Norwegian Sea water which spill over the submarine ridges separating the Norwegian Sea from the rest of the Atlantic. L. V. Worthington pointed out that the view that these overpourings can contribute directly to the formation to-day of North Atlantic deep water seems doubtful on the basis of the new section along 50° N. made by *Discovery II*. On the other hand, there is direct observational evidence of a rather vigorous circulation in the deep water (J. C. Swallow and L. V. Worthington, *Nature*, 179, 1183; 1957) as a result of the measurements of the deep western boundary current under the Gulf Stream made by *Discovery II* and *Atlantis* last Spring; and G. Wüst's (Germany) new computations show high rates of transport in the deep water of the South Atlantic as well.

A map discussion centred about the preparation of a chart of temperature, salinity and dissolved oxygen content at 4,000-m. depth, constructed by E. D. Stroup (United States), and rough working copies were distributed to all participants. This chart contains all the deep data yet published and it is hoped that it will prove helpful to those planning future oceanographic surveys. A chart of temperature, salinity and oxygen content of the Pacific at the 5,000-m. level was presented by W. Wooster and G. Volkmann (United States).

The general picture emerging from these various descriptive studies is that the general flow of water below 2,000-m. depth in the ocean is directed from quite limited areas in the northern North Atlantic and from the shallow shelf areas surrounding Antarctica into the Indian and Pacific Oceans. The regions where water is supplied by sinking to the level beneath 2,000 m. are doubtless quite small, and probably intermittent. On the other hand, the upward flow of water out of the deep ocean evidently occurs in a very widespread manner all over the ocean, and it is presumably this upward flow which prevents the hot water at the surface from gradually working down into the deep water (even at the tropics the warm surface layers are relatively shallow and the temperature of bottom waters is less than 3° C.). The average time of residence of a particle of water between its introduction into the deep water at a source and its eventual upwelling through the 2,000-m. level is estimated at between 400 and 1,200 years. Superposed upon this mean circulation there are evidently rather major perturbations.

A theoretical method for constructing the horizontal field of flow in the abyss was described by H. Stommel (United States), and some experimental studies in a rotating basin, designed to test partially these theoretical ideas, were presented by A. Faller (United States). Unfortunately the three theoretical oceanographers from the U.S.S.R. who were invited to attend the symposium (W. B. Stockmann, P. S. Lineykin and M. Koshljakov) were unable to come to Toronto, but the official delegate, V. G. Kort, kindly read a short abstract of a paper by M. Koshljakov, who is of the opinion that the abyssal circulation is essentially produced by wind, that lateral eddy viscosity is of vital importance, and that the deep flows are almost always in the same direction as surface currents. These views are quite the opposite of those expressed by Stommel, who regards the deep circulation as an essentially heat-driven and salt-driven engine, and viscosity as insignificant dynamically. In general, Stommel considers that the surface flows and deep flows are in opposite directions, except in a few instances where the wind-driven surface layers are forced to flow otherwise. This theory predicts that in the deep water the mean meridional components of velocity are everywhere directed poleward except in the western boundary streams which connect the slow central flow to regions of formation of deep water. It is thus possible to predict the deep counter-currents under the Gulf Stream. Similarly, we can now expect to find a very narrow intense northward current between 3,000 and 5,000 m. over the Tonga–Kermadec Trench, which feeds the entire Pacific with deep water. One hopes that the adherents of these two rival theories of abyssal circulation will be able to develop them quantitatively and in sufficient detail so that future direct measurements, such as those using Swallow's neutrally buoyant floats, will effect a clear-cut decision in favour of one or the other. It is in this way that science progresses.

R. B. Montgomery, M. Pollak and J. Cochrane (United States) presented a temperature–salinity diagram showing the frequency of occurrence of waters of various temperatures and salinities in each of the major oceans separately, and combined as a world-ocean. Two other theoretical papers, not specifically related to the topic of deep circulation, were read at the Symposium: a study of the formation of multiple currents in flow in a divergent channel under the influence of rotation (B. Saint-Guily, France) and a method for computing actual currents from the geostrophically computed currents in the presence of uniform vertical eddy viscosity (K. Hidaka, Japan). Papers by M. Uda (Japan), K. Yoshida (Japan) and A. E. Maxwell (United States) were read in title only.

H. STOMMEL

NEWS and VIEWS

The Artificial Earth Satellite

THE successful launching of an artificial Earth satellite ranks as a technical achievement of the first magnitude and an event of great scientific interest. From the early observations on the 20 Mc./s. and 40 Mc./s. signals transmitted by the satellite, the orbit appears to be at a mean altitude of 350 miles with a mean speed of about 24,800 ft./sec. The orbit is slightly elliptical, in a plane inclined at about 65° to the equator. It is to be expected that, as a result of the Earth's oblateness, the orbital plane will rotate slowly about the Earth's axis at about 2¼° a day, and in a direction opposite to the Earth's rotation. The major axis of the orbital ellipse will also regress backwards, relative to orbital direction, at less than ¼° per day. It is to be hoped that the radio-interferometer observations, coupled with the theoretical orbital data just quoted, will allow the computation of sufficiently accurate orbits to facilitate further accurate observations by optical means.

At the time of writing, it is difficult to forecast the total life-time of the satellite since the density of the atmosphere is known only very imprecisely at heights of 250 miles and higher. Assuming a value of 10^{-11} times the density at sea-level, one may estimate that a satellite with perigee at 250 miles should survive for about a month. Although theoretical computations of aerodynamic drag, heat protection and heat-sink characteristics suggest that safe re-entry to the Earth's atmosphere should be feasible, recovery of an intact satellite and its instruments is likely to prove a formidable technological problem. The warm congratulations of all those engaged in the applied science of aeronautics and rocket propulsion must go to the Soviet scientists and engineers involved in the satellite project. Future satellite launchings are awaited with the utmost interest.

Paul Instrument Fund Awards

AWARDS of grants by the Paul Instrument Fund Committee have been made as follows: £2,700 to Prof. G. F. J. Garlick, professor of physics in the University of Hull, to enable him to carry out studies of phosphors and photoconductors with the view of the development of solid state light image amplifiers or converters; £2,000 to Dr. H. H. Hopkins, senior lecturer in physics (technical optics), Imperial College of Science and Technology, London, for continuation of the construction of a static scanning fibrescope, the aim of which is to provide a flexible unit capable of transporting optical images along its length; £100 to Dr. D. Gabor, Mullard reader in electronics, Imperial College of Science and Technology, making a total grant of £1,900 for work on a new type of Wilson cloud chamber in the form of a resonant microwave cavity in which time marks are applied to the particle tracks at equal intervals (see p. 746 of this issue of *Nature*). The Paul Instrument Fund Committee, composed of representatives of the Royal Society, the Physical Society, the Institute of Physics and the Institution of Electrical Engineers, was set up in 1945 "to receive applications from British subjects who are research workers in Great Britain for grants for the design, construction and maintenance of novel, unusual or much improved types of physical instruments and apparatus for investigations in pure or applied physical science".

Rockefeller Institute Quarterly

THE Rockefeller Institute for Medical Research is now issuing, primarily for present and former members of the Institute, the *Rockefeller Institute Quarterly*, the first issue being dated March 1957. It is intended to provide background information of the current work of the Institute and its plans for future development. The first issue contains a brief account of the research programme of the Population Council, the Medical Division and Laboratory of which have been housed at the Institute since September 1954. The Laboratory also assists in the diagnosis of reproductive defects in men by examining testicular biopsies and has developed a technique for determining genetic sex by examining somatic cells such as those in the skin or on oral smears. There is also a Demographic Division which seeks to promote the scientific study of population problems. The Abby Aldrich Rockefeller Hall, which is nearing completion, is to provide a social and residential centre for visiting scientists from all over the world and for the Institute faculty. Extensive changes in the facilities of the Institute buildings, which are nearing completion, will provide for Dr. F. Lipmann's biochemistry laboratory and laboratories for Dr. E. L. Tatum's work on the biochemical genetics of micro-organisms. There are also notes on the Institute's joint programme with the National Academy of Sciences and National Research Council to assist Hungarian scholars, and on the establishment of the post of Administrative Associate for Information Services, as well as lists of appointments and distinctions.

Information Service on Psychopharmacology

A CLEARING house of information on psychopharmacology is being established by the Psychopharmacology Service Center of the U.S. National Institute of Mental Health. An extensive collection of the literature in this field, including pharmacological, clinical, behavioural and experimental studies of the ataraxic, psychotomimetic and other centrally acting drugs, will be classified and coded to enable the staff to answer a wide variety of technical and scientific questions. As soon as enough materials have been assembled, the Center plans to offer bibliographical and reference services as well as the preparation of critical and analytical reviews of special topics in the field. In order to accelerate the growth of the literature collection, the Center invites persons working in the field to provide three copies of any papers that deal with their work—whether reprints, pre-publication manuscripts, progress reports, informal mimeographed reports, papers read at meetings, or abstracts. Letters outlining work in progress would also be welcome. Any restrictions that authors may wish to place on the Center's use of their papers will be strictly observed. All materials should be addressed to the Technical Information Unit, Psychopharmacology Service Center, National Institute of Mental Health, 8719 Colesville Road, Silver Spring, Maryland.

Search for and use of Natural Resources

Impact of March 1957 contains an article by J. Gray, "Technology and the Quest for Materials", which is a timely corrective to the common tendency to over-simplify the issues in controversy on population and resources and the implication of technical changes. Mr. Gray emphasizes the need to plan research ahead rather than continue to rely on the haphazard reactions of private enterprise, but he points out that while all the available evidence suggests that the demand for materials will continue to rise sharply in the next few decades, the urgency of this need is still debatable. The great increase in the consumption of leading metals since 1880 is due to the industrialization of a handful of countries: nine-tenths or more of the world's pig iron, copper, lead, zinc and tin, outside the Communist countries, are consumed in Europe, the United States, Canada, New Zealand, Australia and Japan, but it is probable that the under-developed countries will only slowly affect world demand. To keep production per head of population at the present level, however, requires an increase of nearly 3 per cent per annum in Latin America, 2 per cent in Asia and Africa, and at least 1·5 per cent in North America, Australasia and the U.S.S.R. Mr. Gray suggests that among the problems which most need examination in this context, regardless of cost or immediate return, are substitutes for coal and base metals, the use of alloying metals, new sources of plastics, new fuels for road and air transport and the scope for little-used materials. As regards conservation of resources, the two most obvious steps are to inspire and stimulate interest in design, and the systematic use of scrap. More serious is the need for research on methods of ore dressing and extraction, but while there is room for more conscious planning of prospecting, there are difficulties both on the national and the international plane, chiefly financial and nationalistic. The main hope of increasing the supply of agricultural raw materials lies in increasing the yield per acre.

Information and Communication

A PAPER by Dr. H. Coblans on "New Methods and Techniques for the Communication of Knowledge" in the *Unesco Bulletin for Libraries* of July (Paris: Unesco) is a first step in a long-term programme of study, experiment and development in a field which is becoming a principal interest of Unesco. Starting from discussions and conclusions reached at the Royal Society Scientific Information Conference, the Unesco International Conference on Science Abstracting and the Unesco Conference on the Improvement of Bibliographical Services, Dr. Coblans considers first the new techniques and particularly their use by the Gmelin-Institut fur anorganische Chemie, the Centre National de la Recherche Scientifique (Paris) and the Chemical–Biological Centre, Washington; he then suggests that costing studies for definite subject-fields on an operational basis should be stimulated in the major countries in which mechanical selectors are available. Unesco should commission a critical study of the potentialities of the apparatus described in the Federation of International Documentation Manual, indicating its value and limitations for the main uses in libraries and documentation work. He also recommends the issue of international lists of translations of periodical articles, using the best available mechanical techniques, the establishment in each country or suitable region of at least one punched-card unit with photo-offset equipment for the production of the lists and indexes as needed, and the compilation of a manual of the practice and organization of such services, as well as the subsidizing of research on the production of equipment more suited for the production of these lists. Unesco should also organize an international conference of experts from all patent offices to discuss mechanization, and publish in its proceedings an authoritative summary of the state of present knowledge in this field. In collaboration with the International Federations in Bibliography, Pure and Applied Sciences and Social Sciences, Unesco should also establish and maintain the administrative procedures required to link national and international services in the field of communication of knowledge.

With regard to the older techniques, Dr. Coblans suggests that international organizations should arrange to send their documents to the relevant abstracting periodicals, that in each country there should be one overall social science centre to receive lists of specialists, research in progress and information about conferences and the location of unpublished material, and that the Unesco Social Science Clearing House should co-ordinate the activities of all such centres. He also advocates a long-term study of the adequacy of the scientific periodical as a method of communication, a survey, with the help of the Abstracting Board of the International Council of Scientific Unions, of the extent to which the major abstracting and indexing services in the natural sciences cover articles in annual reviews and technical research reports, the issue of regular lists of published proceedings of international conferences, and a conference on the production and distribution of literature on nuclear energy.

Writing and Searching

Two recent articles in *Research* merit the close attention of every postgraduate research student and young research worker. The first, entitled "A Note on the Writing of Scientific Papers and Theses" (10, 168; May 1957), contains the substance of a lecture delivered at the Atomic Energy Research Establishment, Harwell, by Dr. W. Hume-Rothery. Though it is usual to give constant supervision during the course of a student's research work, very rarely is training given in the important task of writing and preparation of the subsequent report for publication. It is only too well known how poor is the presentation of many contributions to scientific journals. In his advice, Dr. Hume-Rothery adheres to traditional lines. He gives several examples to illustrate the more common faults, emphasizes the importance of conciseness and discusses how to make a paper interesting and clear. It is recommended that experimental results should be so displayed that the reader may see their general nature and, in addition, the exact values to within the limits of experimental accuracy. In this regard Dr. Hume-Rothery deplores the regulations of some journals against the showing of results in both tabular and diagrammatic form.

The second article, "Searching the Literature", by M. A. Short (10, 313; August 1957), although concerned specifically with the literature of physical and inorganic chemistry, nevertheless contains much of value to all chemists and physicists. In making the survey of the relevant literature before a research project is undertaken, there are two conflicting factors—speed and thoroughness—and some balance has to be struck between them. Dr. Short provides an excellent working guide for the ordinary research worker on how best to go about his search systematically. The main chemical and physical libraries in London; the various abstracting journals and their coverage; and the foreign periodicals which are available in an English translation are listed, and in appendixes details are given of suggested treatises and handbooks to be consulted and the titles of the journals of major importance published in the years prior to 1875. In conclusion, Dr. Short gives some brief but interesting advice about how to keep up to date, and how to record the information obtained from the search in an easily available form.

National Institute of Agricultural Botany

THE report of the Council of the National Institute of Agricultural Botany for the year 1956 has now been published (The Secretary, N.I.A.B., Huntingdon Road, Cambridge. 2*s*.). During the year under review there was some reorganization of the work, and a new section, the Multiplication Branch, is now responsible for the increase of pure stocks of seed bred by the official plant breeding institutes. These include cereals and sugar beet from the Cambridge Plant Breeding Institute, grasses and clovers from the Welsh Plant Breeding Station, brassicas and onions from the National Vegetable Research Station, and hybrid tomatoes from the John Innes Horticultural Institution. The remainder of the Crop Improvement Branch is now more appropriately named the Trials Branch. Some 331 acres of stock seed crops of the Aberystwyth strains of grasses and clovers were harvested by the new Multiplication Branch and a further 640 acres by the Welsh Plant Breeding Station, the newly erected herbage granary coming into use for the first time. Interim comments on forty-five cereal varieties which have been tested for two or three years are reported by the Trials Branch and an account given of its work on vegetable crops, which has included group classifications of named seed stocks of brussels sprouts and carrots. Further expansion is reported by the Seed Production Branch. 63,000 acres of seed crops were approved under the cereal field approval scheme, while under that for herbage and seed certification, 90 per cent of all eligible crops of Aberystwyth strains of grasses and clovers were entered for the national comprehensive certification scheme in the first year of its operation. The total number of samples received by the Official Seed Testing Station was very similar to that of the previous year, the good harvesting conditions of 1955 being reflected in the high proportion of clover samples sent in.

Transference of Rust-resistance to Bread Wheats

IT is known that some species in the genera *Agropyron* and *Aegilops* are highly resistant to the rusts which attack wheat. One way of making practical use of this novel source of resistance is to transfer chromosome segments containing genes for resistance from the wild species to wheat by the translocation of small chromosome segments using X-radiation. Sears (Brookhaven Symposia in Biology, No. 9, 1956) succeeded in transferring resistance to leaf rust from *Aegilops umbellata* to wheat, and Elliott (*J. Hered.*, 48, 77; 1957) has now accomplished the transference of resistance to the black rust of wheat from *Agropyron elongatum* (tall wheat grass) to the common bread wheat. Tall wheat grass is a 7*x* (heptaploid) species. The first step was to cross it with 6*x* (hexaploid) wheat. After a few segregating generations, stem resistance was stabilized at the octaploid level. A resistant octaploid was then pollinated by a susceptible wheat, and the hybrid seeds were irradiated in various ways. A single rust-resistant wheat-like plant, which was shown to be hexaploid and easily crossed with ordinary wheat, was isolated from the second generation after X-irradiation with a dosage of 18,000 r. units. All the sister plants were susceptible except for two weak, sterile grass-like plants. The resistant plant bred true to resistance in the next and subsequent generations. Cytological examination of crosses between the resistant form and a susceptible hexaploid wheat indicated that at least three chromosomal interchanges were involved, and that the presumed translocations were small and probably intercalary. This material cannot, as it stands, serve as a new commercial variety, since it falls short of the desired standards for milling and baking quality. The important thing about it is that it demonstrates a new method of combating a series of pathogens which are a menace to an essential food crop.

Meteor Orbits and Rainfall

E. G. Bowen has a paper on "A Prediction of a Meteor Orbital Period" in *The Observatory* (77, 898; 1957), in which he suggests that meteoritic dust has a nucleating effect which leads to heavy precipitation approximately thirty days after the dust enters the top of the atmosphere. Although the majority of meteorologists have opposed this hypothesis, contending that the results are a chance phenomenon and also that there are no physical grounds for expecting a connexion between meteor showers and rainfall, Bowen emphasizes that if the hypothesis is correct there exists in the meteorological records an impressive collection of information from which, in certain cases, a considerable amount of evidence about past meteor activity might be derived. Bowen refers to a paper of his in *J. Met.*, 13, 142 (1956), which shows that if the daily rainfall of the first five weeks of the year is totalled for about 250 stations in different parts of the world over a period of fifty to sixty years, it does not result in a smooth curve but exhibits distinct peaks on January 12 and 22 and February 1. As is well known, these dates are about thirty days later than the Geminid, Ursid and Quadrantid meteor showers, respectively. While the records from which the curve was compiled included a fair sample of data from the northern hemisphere, the same did not apply to the southern hemisphere; but many more data from the latter have now become available, the samples coming from fifty stations in Australia, fifty in New Zealand, ten in South Africa and ten in the Argentine. From the data from these stations another curve has been drawn and it shows peaks which closely correspond on practically the same dates with those in the previous curve. It is admitted that a sharp difference of opinion exists among meteorologists regarding these peaks, the majority maintaining that a rainfall curve of this type is a smooth horizontal line with chance fluctuations about the mean, but Bowen contends that they have a real significance (see also *Nature*, 177, 1121; 1956).

Plastic Mounts for Biological Display

In the issue of the *Museums Journal* for September, Dr. Blodwen Lloyd, of the Royal College of Science and Technology, Glasgow, describes a method of mounting biological specimens in transparent plastic. This entails sandwiching the specimens between two sheets of plastic, the air being driven out by the application of low heat and pressure. The technique is specially applicable to objects which are virtually two-dimensional, such as herbarium plants, but can also be used for the mounting of specimens in low relief, as, for example, small bones and woody twigs.

The Oliver Bird Trust

In July 1957 a charitable fund was established with the title of the Oliver Bird Trust, the Trustees being Mrs. M. A. Pyke, the Hon. Mrs. Burrell and Dr. A. S. Parkes. The Trust has as its object the advancement of knowledge of methods of fertility control with special reference to the promotion and provision of facilities for tests, clinical trials of systemic methods of contraception as they become available, and in the meantime the improvement of locally-acting spermicides. The Trustees will offer for award in each of the next five years a prize of not less than £250 and an Oliver Bird Medal for laboratory or clinical work bearing on the control of conception. The first prize will be offered early in 1958, and application should be made not later than December 31. They will also arrange two annual Oliver Bird Lectures: one with the aim of promoting in medical and scientific circles recognition of the importance of investigating fertility control; the other to be sponsored by the Society for the Study of Fertility, dealing with the technical aspects of the problem. The first technical lecture will be given on November 6 in the lecture theatre at University Hospital Medical School at 5 p.m. by Dr. T. Mann on "The Biochemical Basis of Spermicidal Activity". Finally the Trustees will set up a Council for the Investigation of Fertility Control, which will work in conjunction with the Family Planning Association and will be responsible for organizing tests and clinical trials. Further information can be obtained from the office of the Trust at 64 Sloane Street, London, S.W.1.

Advisory Group for Aeronautical Research and Development

The seventh general assembly of the Advisory Group for Aeronautical Research and Development of the North Atlantic Treaty Organization will be held on November 25–26 in Washington, D.C. Dr. Theodore von Kármán, chairman of the Advisory Group, will preside over the formal opening of the general assembly at the Shoreham Hotel, Washington, at which Gen. Nathan F. Twining, chairman of the Joint Chiefs of Staff, North Atlantic Treaty Organization, will give an address on the development of air power in the United States. The first session will be devoted to a discussion on the general theme "Towards Higher Altitude", with Dr. Hugh L. Dryden, director of the National Advisory Committee for Aeronautics, in the chair. Introductory talks followed by general discussion will be given on: "Aerodynamics of Low Density Media" by Prof. G. N. Patterson, director, Institute of Aerophysics, University of Toronto; "Propulsion at High Altitudes", by M. F. Florio, technical director, Société d'Etudes pour la Propulsion par Réaction, and Messrs. M. Barrère and R. Siestrunck, Office National d'Etudes et de Recherches Aéronautiques; "Physics of the Stratosphere and Ionosphere", by Prof F. Dieminger, Max-Planck Institute; "High Altitude Flight Testing", by Major I. C. Kincheloe, jun., and H. M. Drake; "Aeromedical Problems of Flight above the Atmosphere", by Col. P. A. Campbell, Air Research and Development, United States Air Force. Reports on the activities of the Advisory Group will be given by the Panel Chairmen and the Director on the morning of November 26.

University News: Birmingham

The following appointments have recently been made in the University of Birmingham: L. Castillejo, to be lecturer in mathematical physics; Dr. G. C. Brock, to be lecturer in civil engineering; Dr. R. J. Allwood, to be temporary lecturer in civil engineering; G. V. Jeffreys and Dr. D. R. Oliver, to be lecturers in chemical engineering; R. W. Snell, to be lecturer in petroleum production engineering; P. D. Allen, to be lecturer in mechanical engineering; and Dr. B. Shaw, to be lecturer in medical biochemistry and pharmacology.

Dr. A. P. Batson, N. E. Booth and Dr. J. D. Hobson have been appointed Imperial Chemical Industries Research Fellows.

Announcements

Prof. Ragnar Granit, of the Medical Nobel Institute, Stockholm, has been awarded the Retzius Gold Medal of the Swedish Society of Physicians. Since 1897 this Medal has been awarded every tenth year, alternately in anatomy and physiology.

The Executive Council of the Commonwealth Agricultural Bureaux has elected Mr. T. Swaminathan, representing India, as chairman, in succession to Mr. C. E. Lambert, who represented the Colonial Territories. Dr. J. G. Malloch, representing Canada, has succeeded Mr. Swaminathan as vice-chairman.

Mr. L. Gosland has been appointed research manager of the Electrical Research Association and Mr. E. E. Hutchings head of the Member Relations Department. Mr. A. M. Cassie and Dr. L. H. Orton will be joint heads of the Switchgear Department, and Dr. G. Mole and Dr. F. Busemann head and deputy head, respectively, of the Transmission and Utilization Department.

Mr. D. R. Barber, formerly assistant to the director of the Norman Lockyer Observatory of the University of Exeter, has been appointed superintendent of the Observatory. Mr. D. L. Edwards, director of the Observatory since 1936, died in September 1956 (see *Nature*, 178, 1028; 1956).

The International Union against Cancer is to award a limited number of travel grants to enable young scientists who do not yet hold senior appointments, but who have already made significant contributions to research on cancer, to attend the 7th International Cancer Congress to be held in London during July 6–12, 1958. Application forms may be obtained from Dr. I. Berenblum, Weizmann Institute of Science, Rehovoth, Israel, to whom all inquiries should be addressed.

Applications are invited for the Helen Putnam Fellowship for Advanced Research, a postdoctoral resident fellowship for women, with research facilities at Harvard University. The research may be in any field related to genetics or mental health, including psychology, child development and other fields of social science. The stipend will be 3,500 dollars a year, with possibility of renewal. Application forms may be obtained from the Secretary of the Graduate School, Radcliffe College, Cambridge 38, Massachusetts. Completed applications should be returned not later than January 15, 1958. Announcement of the award will be made on or before February 15, 1958.

A new scholarship—the Frank Wright Scholarship—which will give the recipient the opportunity for further study in the United States at either the Textile Research Institute, Princeton, or at the Massachusetts Institute of Technology, is to be awarded by the Textile Institute. Candidates must have been born in the United Kingdom and must possess a university degree of sufficient standing for attendance at one of the two American institutions. The recipient of the scholarship will become a candidate there for the Ph.D. degree in chemistry, chemical engineering or mechanical engineering. The duration of the course will probably not exceed three and a half years, and the Fellow will be paid 1,500 dollars in each of the first two years plus 600 dollars tuition fees and 1,800 plus 600 dollars in the third year. The scholarship holder will be expected to give an undertaking to return to the United Kingdom at the conclusion of his course and to work there for a period of at least five years. Further information can be obtained from the General Secretary of the Textile Institute and applications must be returned not later than October 31.

Three scholarships in engineering, of about £450 a year according to circumstances and tenable in the Department of Engineering in the University of Southampton, are to be offered annually by Hoover Ltd. The scheme combines an honours degree course in mechanical and electrical engineering with complementary practical training in production engineering, research and development at the Hoover factory at Perivale. The training tasks are designed to be of a broad engineering nature, characteristic of processes carried out in industry generally in these fields. Training is further diversified by attachments to other factories in Britain and overseas. The student is under no obligation to Hoover Ltd. after graduation, nor is the company obliged to employ the graduate, but it is hoped that a suitable appointment may be available for successful honours candidates. Selection is by an examination, set by the University of Southampton, which is to be held at Hoover Ltd., Perivale, in February of each year. Details of the syllabus may be obtained from the University. Applications, which must be received before December 8, should be addressed to the Education and Training Officer, Hoover Ltd., Perivale, Greenford, Middlesex, from whom further information can be obtained.

LINNAEAN ANNIVERSARY CELEBRATIONS

By Dr. J. RAMSBOTTOM

As was to be expected, the Swedish celebrations of the 250th anniversary of the birth of Linnaeus were befitting to the memory of a world-famous scientist, and a national hero. A new statue—a copy of the one at Stockholm—was set up at Upsala, a medal was struck, telegraph forms bore a fine coloured representation of *Linnaea borealis*, special postage stamps were issued, and numerous works both by and on Linnaeus were displayed in the book-shops.

The celebrations proper began at his birthplace, Råshult, on May 23 (O.S. May 11), his birthday, and May 24, long regarded as such by, for example, the Linnean Society of London, owing to confusion when the Swedish calendar was changed. The University of Upsala, where Linnaeus was professor of medicine and botany (1741–78) and three times rector magnificus, as well as paying special tribute in the end-of-term ceremonies, arranged a symposium on "Systematics of To-day" (May 28–30), which was attended by about thirty foreign guests.

Those attending were welcomed at an opening ceremony in what was formerly the orangery of the old University Botanic Garden by the Rector Magnificus of the University of Upsala and by the Chancellor of the Swedish Universities, in short speeches. Then the president of the symposium, Prof. J. A. Nannfeldt, gave a brief address in which he spoke of Linnaeus's attitude to Nature, his concept of species and the appropriateness of the meeting as part of the Upsala celebrations. Afterwards a walk was taken round the Garden, again arranged as by Linnaeus, and a short visit to the adjoining professor's house, now used as a Linnaean museum. The attractive large yellow-flowered *Corydalis nobilis* was growing abundantly as a weed in the garden, as elsewhere in Upsala: it was introduced among seeds of *Dicentra spectabilis* sent to Linnaeus from Siberia.

The symposium proper was held at the University. Probably most people doubted whether a programme of twenty-seven papers, with discussions, could be crammed into four sessions. Each speaker had been allotted fifteen minutes, and all loyally kept to this, occasionally reminded of the passage of time by a sort of traffic-signal system in full view of the audience, with an accompanying buzz—an international self-denying ordinance with consequent smooth running, and general satisfaction: the improbable had been achieved. The opening paper was by E. Mayr (United States) on "The Evolutionary Significance of the Systematic Categories". The primary object of systematics has always been to permit grouping of the bewildering number of natural entities into collective units—to make order out of chaos. This seemingly purely practical task can be carried out in different ways depending on the basic philosophy adopted. Though the practical aims of taxonomists are still the same as in the time of Linnaeus, the underlying philosophy has changed drastically. There are two essential reasons for this: (1) the acceptance of the theory of evolution and, far more important, (2) the replacement of typological thinking by populations thinking. These are by no means two aspects of the same concept.

A species is a group of interbreeding populations. Individuals of which a species is composed are the visible expression and temporary containers of the 'gene pool' of the species. This pool is sharply limited to genes which can harmoniously combine into genotypes and produce successful phenotypes. Harmonious gene pools require protection against outside disturbance—the so-called isolating mechanisms. The limitation of the gene pool sharply restricts the ecological potentialities of a species. By reason of its limited genetic endowment each species is specialized to a greater or lesser degree: every new gene pool, every incipient new species, and every new species is an ecological experiment; a possibility of entering a new adaptive zone. This is the great evolutionary significance of the species.

There is a certain collective advantage in the stability of phenotypes. There is a 'developmental homoeostasis' which permits of a great deal of genetic reconstruction without major morphological reconstruction. Once a successful phenotype has been evolved there will be an evolutionary tendency to preserve it. There is an optimum phenotype for a particular ecological niche.

Each morphological type is the produce of a long process of adaptation for a specific environment, namely, that occupied by the given taxonomic category. Each taxon is thus not only a morphological phenomenon or a genetic phenomenon, but also an ecological phenomenon. The re-organization of the gene complex which such an evolutionary adaptability entails cannot be reversed.

Julian S. Huxley (Great Britain) spoke on "Grades as an Auxiliary Method in Taxonomy". The aim of most post-Darwinian taxonomy has been to express natural (phyletic) relationships: the taxonomic units (genus, order, class, etc.) are assumed to denote monophyletic groups. Often, however, such groups have turned out to be certainly, or probably, di- or poly-phyletic (for example, Subholostei, Gryphaea). They should, therefore, be called grades, not monophyletic units.

Further, the co-existence, in all evolutionary processes, of improvement (anagenesis) as well as diversification by splitting (cladogenesis) necessitates the erection of a two-way taxonomic system, classifying assemblages by anagenetic *grades* as well as by cladogenetic monophyletic groups, for which the general term *clades* may be suggested.

In point of fact most taxonomic units have been recognized as such because they represent persistent grades of organization, while phylogeny is more speculative and is, for the most part, a matter not of observation but of deduction. In any event, anagenetic units (grades) are just as 'natural' or readily delimitable as monophyletic units (clades). Indeed, many taxa are simultaneously both grades and clades (for example, Amniota, Monotremata, *Dipneumonina*, *Equus*). Others, however, are only (polyphyletic) grades (for example, Metozoa, Teleostei, and various 'genera' such as *Merychippus* or *Cephalaspis*). The human stock is properly definable both as a minor clade (family Hominidae) and a major grade (Psychozoa).

G. Heberer (Western Germany) followed with "Zum Problem den additiven Typogenese"—on much the same general lines as the two previous papers. It was interesting to note the importance all three speakers placed on the researches of the American geologist, G. G. Simpson.

It was now the turn of the cryptogamic botanists, Roger Heim (France) dealing with "Les critères d'ordre chimique dans l'étude des affinités chez les Macromycètes". He examined in what degree the occurrence of certain chemical substances in fungi (either immediate products such as glycogen, chitin and cellulose, mannitol, trehalose, or pigments dissolved in vacuoles and fat globules in cells) can be used for supporting views in the general systematy of Mycetes. He showed that in certain cases—crystallized carotinic chondriocontes of spermatophytes and of fungi—such criteria have no taxonomic value. On the other hand, the presence or absence of a substance in a given group may provide strong confirmatory evidence of its status: such are the intercellular pigments of agarics with coloured spores, diphenylbenzoquinonic pigments. He gave examples of genera in which certain chemical substances are found in some only of the species but where all the species are obviously intimately related. He also gave examples of the strong correlation which can be seen between chemistry and certain anatomical structures. In his view biochemical criteria have a part to play in the controversies, hypotheses and confirmations of systematics, with its ultimate aim of a natural classification.

J. Feldmann (France) in "Remarques sur la Systématique actuelle des Algues" stressed the importance of cytological and biochemical characters for distinguishing large divisions (phyla) of algae as well as for characterizing orders. He showed, as an example, how the utilization of these characters during the past twenty years had brought about the splitting up of the Siphonales, formerly considered to be homogeneous.

Comparing systematics with taxonomy, the aim of which is essentially practical, he showed that in algae the search for natural affinities, the object of systematics, should make use of characters drawn from the living matter itself (morphology of the cellular constituents and biochemical peculiarities) rather than those furnished by morphology, anatomy and mode of reproduction. By convergence such characters can be the same in groups having no real affinities.

R. Tuomikoski (Finland) followed with a research summary, "Über den heutigen Stand der Laubmoossystematik". Mosses are easy to collect and examine under the microscope so that at first their study made good progress along morphological lines. This resulted in their classification becoming more or less stereotyped, and during the past twenty years little research has been carried out to bring it more in line with modern ideas.

R. Pichi-Sermolli (Italy) gave an outline of "The Higher Taxa of the Pteridophyta and their Classification", making several proposals for modification and rearrangement.

The afternoon session opened with a philosophical discussion by B. Rensch (Western Germany) on "Die ideale Artbeschreibung".
